Abstract. The Baltic Sea is a brackish shallow sea, the state of which is determined by the mixing of ~~the~~ freshwater from net precipitation and runoff with the salty water from the North Sea inflows. The ~~climatological~~ freshwater content (FWC) of the [Baltic Sea](#) is calculated from the Copernicus regional reanalysis- [data covering the period 1993–2021](#). The FWC in the [Baltic Sea](#) shows a steady decrease over the past two decades with a linear trend of 23.9 km^3 per year; however, the trend has significant spatial variability. The Gulf of Bothnia has a positive FWC tendency, while the Baltic proper has a negative FWC tendency. Temporal changes of FWC are opposite between the Bothnian Bay in the north and the southern Baltic proper. In the Bothnian Bay, interannual changes of FWC are positively correlated with river runoff and net precipitation and negatively correlated with salt transport. In the southern Baltic proper, the variations of FWC and salt transport through the Danish straits are negatively correlated from 1993 until 2010 but positively correlated thereafter. The seasonal freshwater content reflects the specific hydrophysical conditions of each sub-basin, with northern basins being influenced by ~~the~~ seasonal [river](#) runoff and ice formation [and melting](#), while the southern basins are more responsive to subsurface salinity changes. ~~The total freshwater content in the Baltic Sea shows steady decrease over the past two decades with a linear trend of 23.9 km^3 per year, however the trend has significant spatial variability. In the northern Baltic the freshwater content is influenced by the increase of runoff and decrease of ice formation, which results in positive freshwater content tendencies, while in the southern parts the salty water supply has reduced the freshwater content. due to salt transport through the Danish straits.~~

25

Short Summary. The freshwater content in the Baltic Sea has wide sub-regional variability characterised by the local climate dynamics. The total freshwater content trend is negative due to the recent increased inflows of salt water, but there are also regions where the increase in runoff and decrease in ice content have led to an increase of the freshwater content.

Keywords: [freshwater content](#), [reanalysis data](#), [river runoff](#), [net precipitation](#), [salt transport](#), [Baltic Sea](#)

1 Introduction

30

Climate warming has resulted in the intensification of the global hydrological cycle, but not necessarily on the regional scale (Pratap and Markonis, 2022). The increase of net precipitation over land and sea areas, decrease of ~~the~~ ice cover, and increase of river runoff are the main components of the global hydrological cycle that increase freshwater content (FWC) in the ocean

(Boyer et al., 2007) and decrease ocean salinity. All the components can be directly estimated, but might have significant uncertainties. Instead, the ocean salinity change can be used as a marker of the water cycle change (Durack et al., 2012).

In the case of an open part of the ocean, e.g. a regional sea, using salinity as proxy for ~~the~~ FWC includes an additional blurring aspect, which is water transport through the open boundaries between the basin under consideration and its surrounding area.

35 The impact of water exchange on the changes of ~~the~~ FWC is significant if not dominant. In that case, changes of ~~the~~ FWC may not represent the actual changes of freshwater input from the ~~abovementioned~~above-mentioned sources.

The Baltic Sea is one of the marginal seas where water salinity and FWC are strongly influenced by the water exchange with the North Sea. The Major Baltic Inflows (MBIs) are the most voluminous event-type sources of saline water to the Baltic Sea (Mohrholz, 2018). The frequency and intensity of the MBIs and other large volume inflows have no long-term trends but do

40 have a multidecadal variability of about 30 years (Mohrholz, 2018; Lehmann and Post, 2015; Lehmann et al., 2017; Radtke et al., 2020). Smaller barotropic and baroclinically driven inflows transport saline water into the halocline or below it, depending on the density of the inflow water (Reissmann et al., 2009). The inflows of saline water are forced by winds from the west and outflows by winds from the east.

Direct total input of freshwater to the Baltic Sea consists of river runoff and net precipitation. The total river runoff from the

45 Baltic Sea catchment area shows no statistically significant trend but a variability of about 30 years (Meier et al., 2019a, b) and a pronounced decadal variability of accumulated anomaly of runoff (Lehmann et al., 2022). The variations in runoff explain about 50% of the long-term variability in volume-averaged Baltic Sea salinity (Meier and Kauker, 2003; Lehmann et al., 2022), while the direct dilution of the Baltic Sea water by freshwater accounts for 27% of the interannual variations (Radtke et al., 2020). During 1950-2018, precipitation averaged over the Baltic Sea catchment area had a trend of 1.44 mm year⁻¹

50 (Meier et al., 2022).

Thus, the long-term salinity of the Baltic Sea is determined by saline water inflows from the North Sea (wind forcing) and its dilution with freshwater originating from numerous rivers across the Baltic coast and ~~from the~~ net precipitation (Winsor et al., 2001; Meier and Kauker, 2003; Gustafsson and Omstedt, 2009; Schimanke and Meier, 2016; Lehmann et al., 2022). ~~A specific feature~~

55 There is no clear long-term trend of the mean salinity of the Baltic Sea is the large difference in sea surface salinity between, but there are multidecadal oscillations of about 20 g/kg in Kattegat and 2 g/kg in the Bothnian Bay (Leppäranta and Myrberg, 2009)30 years (Kniebusch et al., 2019). A 30-year variability has been found for the salinity, river runoff, and saltwater inflows (Radtke et al., 2020). The Baltic Sea salinity also has a natural centennial variability (Kniebusch et al., 2019).

A specific feature of the Baltic Sea is the large difference in sea surface salinity, ranging from about 20 g kg⁻¹ in the Kattegat to 2 g kg⁻¹ in the Bothnian Bay (Leppäranta and Myrberg, 2009). Kniebusch et al. (2019) found a positive trend of centennial changes in the north-south gradient of the surface salinity and river runoff in the northern catchment area. Multi-decadal oscillations control the long-term variations of surface salinity and its meridional gradient with a period of about 30 years (Radtke et al., 2020).

60 A common approach is to use salinity to describe the energy and water cycles in the Baltic Sea (Lehmann et al., 2022 ~~and references therein~~; Meier et al., 2022). In this study, instead of using spatially mean salinity of the Baltic Sea, we suggest the

65 concept of ~~the~~FWC (Boyer et al., 2007) for the description of the physical state of the Baltic Sea. Previously, a concept of ~~the~~ FWC has been used to estimate the freshwater budget of the Baltic Sea (Winsor et al., 2001) and for the geographical spreading of spring-time river runoff (Eilola and Stigebrandt, 1998).

The aim of this study is to analyse the changes of the Baltic Sea FWC during the period of 1993–2021. The MBI in 1993 ended the stagnation period with no MBIs that lasted for about 10 years (1983–1993). During the stagnation period ~~the~~salinity was
 70 below average, ~~the~~stratification weakened, and hypoxic area decreased (Lehmann et al., 2022). The period of 1993–2021 includes the third in volume MBI in 2014 (Mohrholz et al., 2015) and ~~a number several~~ of the other barotropic large volume inflows (Mohrholz, 2018). We focus on the changes of the FWC in the whole Baltic Sea, ~~but also in as well as~~ its sub-basins. We investigate the trends in ~~the~~ FWC and observe its seasonal changes. A qualitative explanation of the physical processes behind the dynamics of ~~the~~FWC is provided.

75 2 Data and methods

The BALMFC CMEMS reanalysis product (data ref. 1, Table 1) is calculated using the Nemo-Nordic 1.0 ocean model (Hordoir et al., 2019). The horizontal resolution of the model is approximately 2 nautical miles, and there are 56 vertical levels. Vertical resolution varies from 3 m at the surface ~~up~~ to 10 m below the 100 m depth. The model without data assimilation has been thoroughly validated (Hordoir et al., 2019). The Copernicus model system uses ~~the~~ Localised Singular Evolutive Interpolated
 80 Kalman filter data assimilation method (Liu and Fu, 2018). [A detailed quality assessment of the reanalysis product \(data ref. 1, Table 1\), using K-means clustering algorithm \(Raudsepp and Maljutenko, 2022\), is provided in Appendix A.](#)

Table 1. CMEMS and non-CMEMS products used in this study, including information on data documentation.

Product ref. no.	Product ID & type	Data access	Documentation

3	IOW-THREDDS-BMIP_bmip_rivers_2019-10-10-1; Numerical models and Observations	IOW THREDDS (2019)	Väli et al. (2019)

The FWC is calculated according to Boyer et al. (2007) ~~as following~~

85
$$FWC = \frac{\rho(S_{ref}, T_{ref}, p) \Delta S}{\rho(0, T_{ref}, p) S_{ref} + \Delta S}, \quad [1]$$

$$FWC = \frac{\rho(S_{ref}, T_{ref}, p) S_{ref} - S}{\rho(0, T_{ref}, p) S} \quad (1)$$

where ΔS is a salinity anomaly from reference salinity S_{ref} ($S(x, y, z, t)$ and $S_{ref}(x, y, z)$) are actual salinity and reference salinity, respectively, and x, y, z, t are indexes in zonal, meridional, vertical and temporal dimensions/coordinates, respectively.

The density (ρ) is calculated according to the TEOS10 (IOC et al., 2010). The key issue of FWC calculations lies in how the reference salinity is defined. The climatological range of salinity in the Baltic Sea varies from the fresh/freshwater conditions in the northern and eastern parts up to the oceanic water conditions in the Kattegat. Therefore we follow the Boyer et al. (2007) formulation and calculate the climatological FWC from the three-dimensional temperature (T_{ref}) and salinity (S_{ref}) fields averaged over the period of 1993–2020.

The other widely used formulation of FWC is as follows (e.g. Gustafsson and Stigebrandt, 1996):

$$FWC = \frac{\rho(S_{ref}, T_{ref}, p) S_{ref} - S}{\rho(0, T_{ref}, p) S_{ref}} \quad (2)$$

Both formulations are derived from the concept of the mixing of two water masses with different salinities by using conservation of salt but have different mechanistic approaches, which are explained in detail in Appendix B.

The total volume of freshwater which is needed to add/extracted to bring the ocean state to the level of reference dilute the water with salinity S_{ref} to the salinity S , if $S < S_{ref}$ or should be removed to obtain water with the salinity S , if $S > S_{ref}$, is an integral over different spatial dimensions

For total volume:

$$FWC(t) = \iiint_V FWC(x, y, z, t) dx dy dz \quad [m^3 m^{-3}],$$

$$FWC(t) = \iiint_V FWC(x, y, z, t) dx dy dz \quad [m^3 m^{-3}].$$

A vertical distribution of freshwater/the FWC is calculated as

$$FWC(z, t) = \iint_A FWC(x, y, z, t) dx dy \quad FWC(z, t) = \iint_A FWC(x, y, z, t) dx dy \quad [m^2 m^{-3}],$$

and spatial/horizontal distribution of freshwater/the FWC is calculated as

$$FWC(x, y, t) = \int_D FWC(x, y, z, t) dz \quad FWC(x, y, t) = \int_D FWC(x, y, z, t) dz \quad [m m^{-3}].$$

Where the V and A correspond to the volume and area of the Baltic Sea or its sub-region which are, as shown on Fig 1. The D corresponds to depth from surface to bottom at a specific location.

110

Then the linear trend of the sea ice volume (V_i) over 1993–2020 (28 years) is calculated from the same BALMFC CMEMS reanalysis product (data ref 1, Table 1) based on the LIM3 model configuration (Pemberton et al., 2018, 2017). The ice volume V_i is calculated for each model grid cell (x, y) using the total ice thickness (H_i) and the ice concentration (C_i) as below:

115 $V_i(x,y,t) = H_i(x,y,t) * C_i(x,y,t) * dA(x,y),$

$$V_i(x, y, t) = H_i(x, y, t) * C_i(x, y, t) * dA(x, y)$$

where dA is the area of each grid-cell.

~~The hourly~~Hourly precipitation and evaporation data ~~has~~have been extracted from the ERA5 reanalysis (data ref 2, Table 1) from the period of 1993–2020. ~~The net~~Net precipitation was calculated by subtracting evaporation from precipitation.

120 ~~Further~~Thereafter, the net precipitation was interpolated ~~on~~to a ~~2 nautical mile grid (ocean reanalysis model) grid,~~ and total net precipitation was estimated for the wet grid-cells of each sub-basin ~~shown in~~(Fig. 1–). ~~The net precipitation anomalies were calculated relative to the period 1993–2020.~~

The total runoff from the Baltic Sea rivers was estimated from the river discharge database (data ref 23, Table 1) of the Baltic Model Intercomparison Project (~~Väli~~Gröger et al., ~~2019~~2022). The runoff ~~to each sub-basin was calculated by summing the~~ runoffs from each river ~~was accumulated~~discharging to the corresponding sub-basin (Fig. 1). ~~The runoff (Fig. 1.) data covered the period 1993–2018,~~ and the ~~accumulated anomaly of the annual runoff was~~anomalies were calculated ~~for~~relative to the ~~same~~ reference period ~~of 1993–2018.~~

130 ~~Salt transport was estimated by calculating the salt flux at the boundaries of each sub-basin (Fig. 1 for the location of the transects). Daily salt transport through each transect was calculated as a salinity and perpendicular velocity product. The annual mean salt transports were calculated by averaging the transects of daily transports over each year and later integrated over the vertical and corresponding horizontal dimension. The positive direction is determined according to the estuarine transport definition, i.e. inflow is from the ocean and outflow is from the head of the estuary.~~

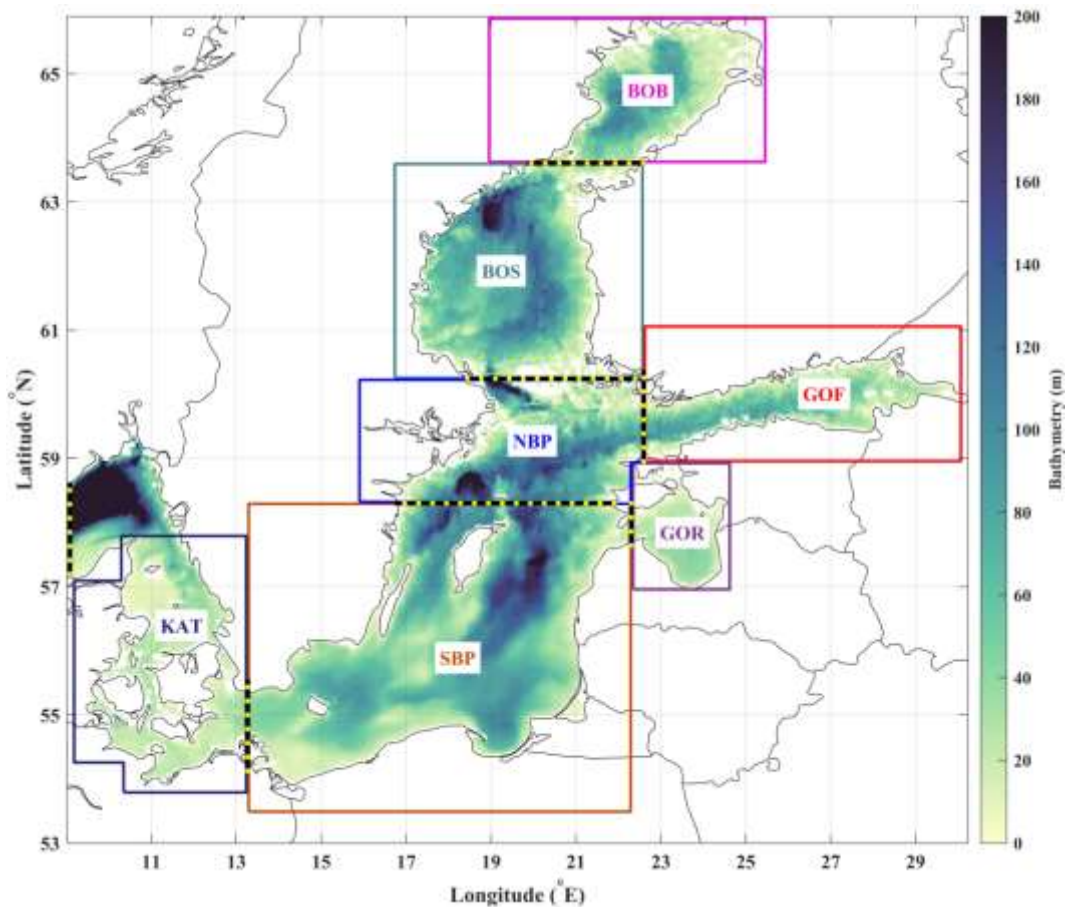

Figure 1. Map of the Baltic Sea depth distribution (data ref. 1., Table 1). Boxes indicate the boundaries used to calculate the freshwater content for different sub-basins. The transects used to calculate salt transport between sub-basins are represented by yellow-black dash-lines. The abbreviations for the sub-basins are as follows: KAT (Kattegat), SBP (Southern Baltic Proper), NBP (Northern Baltic Proper), BOS (Bothnian Sea), BOB (Bay of Bothnia), GOF (Gulf of Finland), GOR (Gulf of Riga).

3 Results and Discussion

Time series of the FWC and linear trends of the Baltic Sea and its sub-basins are presented in Fig. 2. Even if the calculated trends are not statistically significant, they provide information about the tendency of FWC changes. The FWC of the Baltic Sea has a negative trend of $-23.9 \pm 0.7 \text{ km}^3 \text{ /y}^{-1}$ ($p < 10^{-3}$) superimposed by irregular multi-year/decadal variations (Fig. 2a). The trend is variable over the whole Baltic Sea- (Fig. 2). It changes sign from positive in the northern sub-basins to neutral in the eastern sub-basins and to negative in the central and southern sub-basins (Fig. 2). The decrease of the FWC in the southern Baltic Proper (Fig. 2) contributes the most to the overall decreasing trend of the FWC in the Baltic Sea. Detailed spatial distribution of the trends shows in the Baltic Sea, we see opposite temporal regimes of the

FWC in the Bothnian Bay and in the Baltic Proper, with the Bothnian Sea as being the transition area (Fig. 3a3). Although there is no trend in the Gulf of Finland as a whole (Fig. 2), the eastern part has a small negative trend, while the western part shows a small positive trend. The shallow Gulf of Riga has a negligible trend. The trends vanish in the southwestern Baltic Sea and in the Kattegat area (Fig. 3a)–3).

150

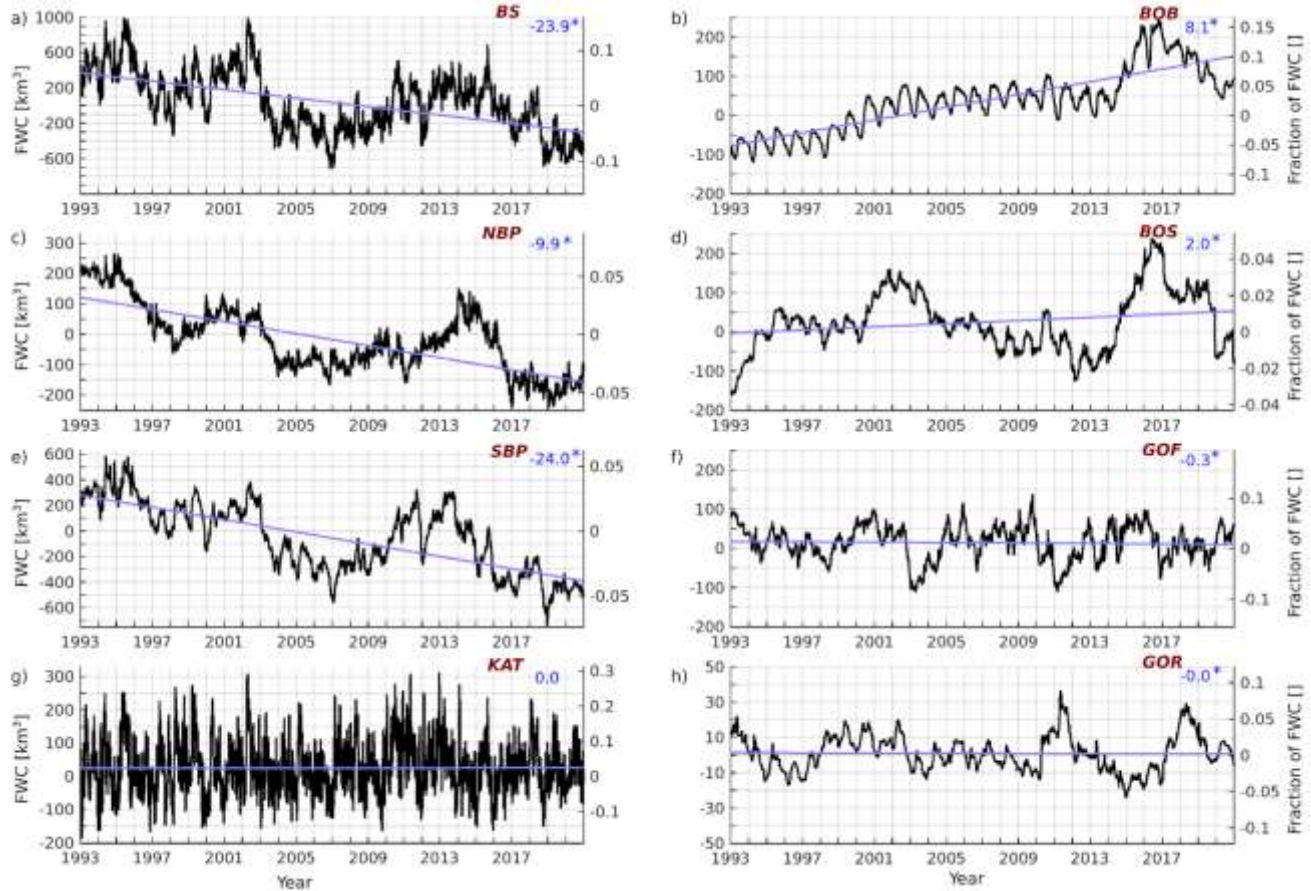

Figure 2.

The range of variation of the FWC differs about an order of magnitude between the sub-basins (Fig. 2) due to different water volumes of the sub-basins. When normalized to the corresponding volume of the sub-basin, we can see that the variations of the FWC affect 10% of the volume of the Baltic Sea (Fig. 2a). The variability of normalised FWC is highest in the Kattegat, relatively high in the Bothnian Bay and the Gulf of Finland and lowest in the Bothnian Sea (figure 2, figure 3b).

155

Freshwater content time series in the Baltic Sea (a) and in different sub-basins (b-h). The trend of FWC in the corresponding basin is shown in the upper right corner ($\text{km}^3 \text{ year}^{-1}$, asterisk $p > 0.05$) and plot using the blue line. The abbreviations for the sub-basins are as follows: BS (Baltic Sea), NBP (Northern Baltic Proper), SBP (Southern Baltic Proper), KAT (Kattegat), BOB (Bay of Bothnia), BOS (Bothnian Sea), GOF (Gulf of Finland), GOR (Gulf of Riga). (data ref 1, Table 1)

160

Figure 3. Spatial distribution of depth normalized FWC trends, with zero-isoline highlighted in black.

165 The spatial distribution of the trends indicates a possible coherence of salinity dynamics in different sub-basins, which is checked further on by calculating correlation coefficients between the basins. The correlation coefficients calculated pairwise between detrended FWC time series (Table 42) show a high positive value between the southern and northern Baltic proper (R=0.8) and between the Bothnian Bay and the Bothnian Sea (R=0.6), while the correlation between the Bothnian Bay and southern and northern Baltic proper is negative (R=-0.6). This suggests that although temporal variability is opposite, the dynamics of FWC are linked over the Baltic Sea.

170

Table 2. Correlations table of the FWC between the sub-basins (Fig. 1) of the Baltic Sea (data ref. 1, Table 1).

Time The abbreviations for the sub-basins are as follows: KAT (Kattegat), SBP (Southern Baltic Proper), NBP (Northern Baltic Proper), BOS (Bothnian Sea), BOB (Bav of Bothnia), GOF (Gulf of Finland), GOR (Gulf of Riga).

	<u>BS</u>	<u>BOB</u>	<u>BOS</u>	<u>GOF</u>	<u>GOR</u>	<u>KAT</u>	<u>NBP</u>	<u>SBP</u>
<u>BS</u>	1.00							
<u>BOB</u>	-0.38	1.00						
<u>BOS</u>	0.06	0.57	1.00					
<u>GOF</u>	0.11	0.01	-0.08	1.00				
<u>GOR</u>	0.13	=	0.03	-0.07	-0.09	1.00		
<u>KAT</u>	0.42	=	0.04	-0.03	-0.10	0.30	1.00	
<u>NBP</u>	0.78	=	-0.22	0.28	-0.17	0.01	1.00	

		<u>0.64</u>						
<u>SBP</u>	<u>0.88</u>	<u>0.65</u>	<u>-0.25</u>	<u>-0.08</u>	<u>0.13</u>	<u>0.21</u>	<u>0.79</u>	<u>1.00</u>

175 Horizontal transition of the trends from positive to negative points to the three-dimensional structure of the FWC variability field. Therefore, time-depth variations of the FWC in each sub-basin ~~are shown~~ were calculated (Fig. 4). Vertically, in Fig. 4, ~~in~~ the whole Baltic Sea, ~~the~~ FWC is the most variable in the halocline layer and beneath it (Fig. 4a). Vertical distribution of the trends shows the absence of the trend in the upper layer of 50 ~~m~~, but strong negative trend within and below the halocline. Thus, the decrease of the FWC in the whole Baltic Sea is mostly ~~caused~~ contributed by the drop of the FWC below the upper

180 mixed layer. The variability as well as negative trends are strongest in the southern and the northern Baltic Proper (Fig. 4e, c). ~~The decrease of the FWC is explained by the saline water transport from the North Sea to the~~ Moving further northward and eastward in the Baltic Sea ~~by the Major Baltic Inflows (Mohrholz, 2018), large barotropic inflows (Lehmann et al., 2017) and smaller inflows of barotropic origin (Lehmann et al., 2022).~~ ~~The~~, we can notice that the ~~negative trend extends~~ tendencies are present only in the deeper layer (deeper than 50 m) of the Gulf of Finland and ~~in the~~ Bothnian Sea (Fig. 4f, d). On the other

185 side, there is a strong positive trend of the FWC in the Bothnian Bay and in the upper 50-meter layer of the Bothnian Sea (Fig. 4f, d). ~~Deep layer water~~ 4b, d). It is relevant to note that a positive tendency in the FWC is seen in the layer of 10–50 m in the Gulf of Finland ~~originates from the sub-halocline layer (110–120 m) of the central Baltic Proper (Liblik et al., 2018).~~ ~~Marginal decreasing tendency of the FWC in the Bothnian Sea is explained by the small fraction of the more saline deep water flowing in over the sills between the~~ (Fig. 4f). In the northern Baltic Proper ~~and the Bothnian Sea (Lehmann et al., 2022).~~ In the upper

190 layer of 50 m, the variability of the FWC is the highest in the Bothnian Bay. There is a strong positive trend that extends down to the bottom of the sub-basin (Fig. 4b). The positive trend of FWC in the upper layer is seen in the Bothnian Sea and in the Gulf of Finland. In the Gulf of Riga the variability is moderate and the trends are negligible. We would like to note that in the northern Baltic Proper, the trend is absent in the upper layer of 30 ~~m~~, but turns negative in the surface layer of the southern Baltic Proper. In the Gulf of Riga, the variability is low, the trends are negligible and do not show systematic vertical

195 distribution.

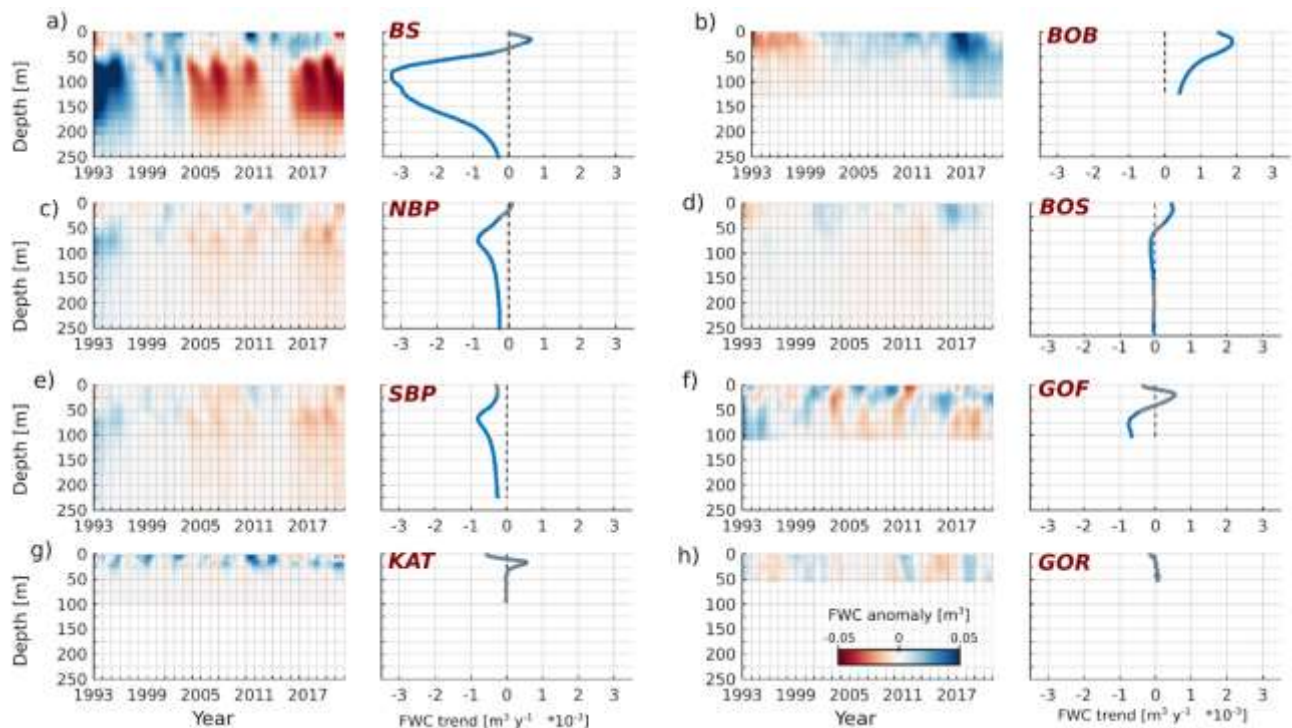

Figure 4. Vertical distribution of horizontal mean FWC anomaly and corresponding trends for each Baltic Sea sub-basin. Trends with statistical significance less than 5% (p -value <0.05) are shown as grey-shaded. The abbreviations for the sub-basins are as follows: BS (Baltic Sea), NBP (Northern Baltic Proper), SBP (Southern Baltic Proper), KAT (Kattegat), BOB (Bay of Bothnia), BOS (Bothnian Sea), GOF (Gulf of Finland), GOR (Gulf of Riga). (data ref. 1, Table 1)

FWC exhibits noticeable irregular decadal variations over time, as shown in Fig. 2 and 4. To understand the interannual variability of FWC, we calculated a time series of river runoff, net precipitation, and salt transport through the cross-sections between the sub-basins of the Baltic Sea (Fig. 1; Supplement). Our aim is to examine the co-variability of these factors and the FWC response of both the entire Baltic Sea as well as its sub-basins. To accomplish this, we present a time series of detrended standardised yearly variables on Figure 5.

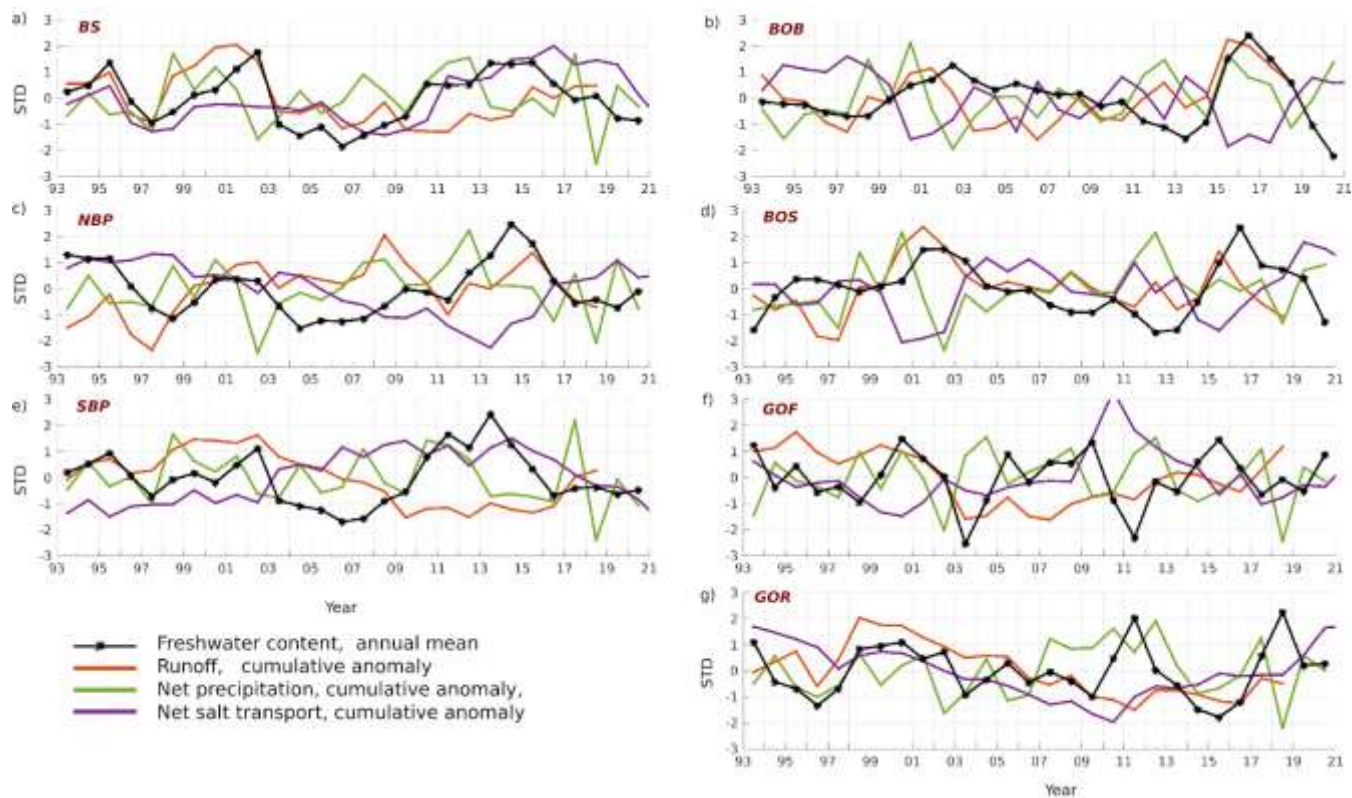

Figure 5. Normalized time series of detrended annual mean FWC (black asterisk), runoff, net precipitation and net salt fluxes. The abbreviations for the sub-basins are as follows: BS (Baltic Sea), NBP (Northern Baltic Proper), SBP (Southern Baltic Proper), BOB (Bay of Bothnia), BOS (Bothnian Sea), GOF (Gulf of Finland), GOR (Gulf of Riga). (data ref. 1, 2, 3, 1; Table 1)

210 For the entire Baltic Sea, the study period can be divided into two sub-periods. From 1993 to 2003, i.e. the first period, changes in the FWC of the Baltic Sea correlated with freshwater sources, namely net precipitation and river runoff (Fig. 5a).

To explain the trend in the upper layer we have calculated freshwater supply by the rivers and by net precipitation. Additionally, we consider the decrease of the ice volume as a potential freshwater source. In the Bothnian Bay, a large positive trend in FWC could be qualitatively explained by the negative trend of ice volume (Fig. 3e). The negative trend of the ice volume is also

215 seen in the eastern part of the Gulf of Finland (Fig. 3c), where FWC showed a positive tendency (Fig. 3a). Thus, warming of the winters (Kotta et al., 2018) could cause a decrease of the ice volume and increase of the FWC in the northern and far eastern parts of the Baltic Sea. In support of this hypothesis Garric et al. (2018) have shown that decrease in the ice volume in the Arctic is correlated with the increase of the FWC. A tendency of increasing river runoff contributes to the FWC in the Bothnian Bay and in the Gulf of Finland (Fig. 5f). Net precipitation has increased over the Bay of Bothnia and over the

220 Bothnian sea (Fig. 5b). A prominent example is the period from 1997 to 2003. Meanwhile, the salt transport to the Baltic Sea remained relatively low. Since 2004, i.e. the second period, we have observed a coherent relationship between salt transport

and the FWC in the Baltic Sea, which is difficult to explain. We may speculate that an increase in net precipitation might trigger an increase in the FWC between 2007 and 2012, while river runoff has no effect.

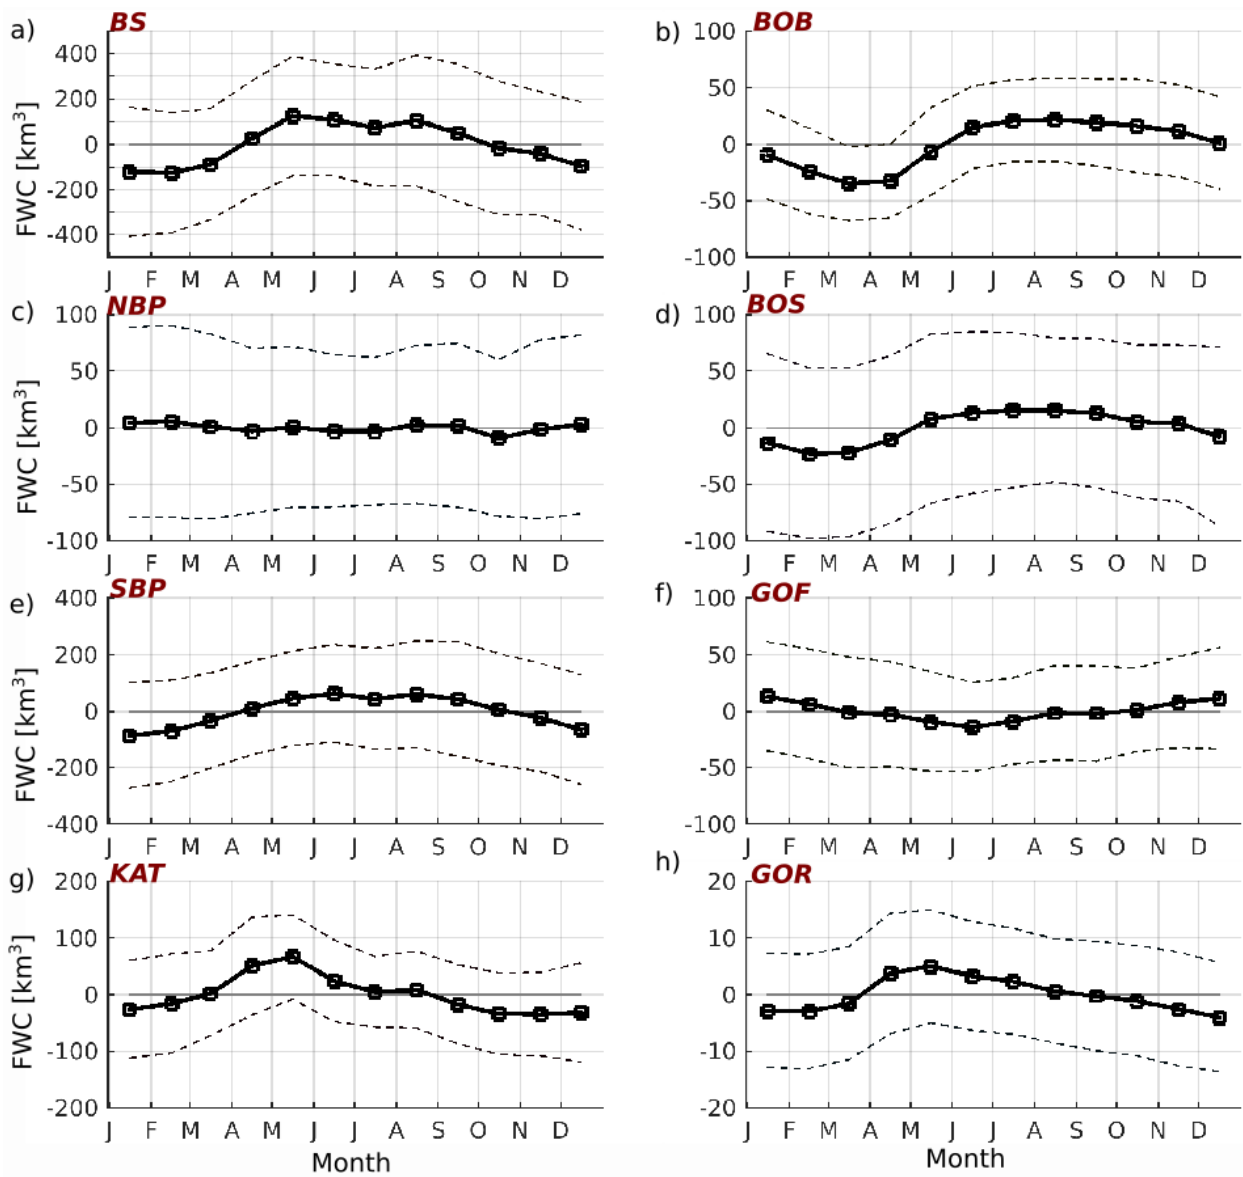

The changes in the FWC of the entire Baltic Sea are influenced by the changes occurring in its sub-basins, resulting in a complex integrated effect. This is illustrated by the simultaneous positive trend of FWC in the northern Baltic Sea and negative trend in the southern Baltic Sea (Fig. 2) as well as their negative correlation (Table 2). Hence, it is necessary to examine the changes in variables separately for each sub-basin. It is important to note that while the FWC, net precipitation, and river runoff for the entire Baltic Sea represent the sum of contributions from each sub-basin, the net salt flux does not represent an integrated value.

We specifically focus on two sub-basins: the southern Baltic Proper, which is characterised by saltwater dominance, and the Bothnian Bay, which is characterised by freshwater dominance. The variations in the southern Baltic proper differ in several features from the variations in the whole Baltic Sea. The southern Baltic Proper exhibits two distinct periods (Fig. 5e), which is qualitatively similar to the entire Baltic Sea, but the periods do not coincide temporally. The first period spans from 1993 to 2007, while the second period extends from 2008 until the end of recorded data. In the first period, FWC, net precipitation, and river runoff show positive covariation, while the flux exhibits a negative covariation pattern. In the second period, there is positive covariation between FWC and salt flux and partially net precipitation, but the pattern is reversed for river runoff. In the Bothnian Bay, there is positive covariation between FWC, net precipitation, and river runoff but negative covariation with salt flux (Fig. 5b). In the northern Baltic Proper and the Bothnian Sea, the main pattern is negative covariation between FWC and salt flux (Fig. 5c and 5d). Changes in net precipitation and river runoff generally support changes in FWC, but the variability pattern remains complex.

The Gulf of Finland (Fig. 5f) and the Gulf of Riga (Fig. 5g) do not exhibit a well-defined pattern in the variability of the variables. In the latter basin, the changes in FWC align with the changes in river runoff from 1993 to 2009 but not thereafter. In the Baltic Sea as a whole there is no trend in the net precipitation (Fig. 6a) nor in river runoff (Fig. 5a). The seasonal dynamics of FWC further emphasise the decoupling of the northern and southern sub-basins of the Baltic Sea (Fig. 7)-effect of freshwater discharge in the northern basins and salt transport in the southern basins of the Baltic Sea (Fig. 6). In the whole Baltic Sea, FWC is low in autumn and winter but high in spring and summer (Fig. 6a). Qualitatively, low FWC could be explained by high salt transport in autumn and winter (Fig. 7c) accompanied by low river runoff (Fig. 7a), but this is interfered with by high precipitation in autumn (Fig. 7b). Contrarily, the high FWC could be explained by high river runoff and low or even negative salt transport in spring and summer. Indeed, net precipitation is low in that period. The Gulf of Bothnia has low FWC in winter and early spring and high FWC in summer and autumn (Fig. 6b,d). The seasonal course is more pronounced in the Bothnian Bay (Fig. 6b) than in the Bothnian Sea (Fig. 6d). In the Gulf of Bothnia, the decrease of FWC in winter could be associated with the freezing of seawater. The minimum FWC is reached in March and April in the Bothnian Bay while the lowest FWC in the Bothnian Sea is in February and March. These months coincide with the months of maximum sea ice extent in these basins (Raudsepp (Fig. 7f). An et al., 2020). During the ice melting period from April to June FWC starts to

255 increase- of the FWC in the Bothnian Bay in spring coincides with the melting of sea ice (Fig. 7f), high river runoff (Fig. 7a) and negative salt transport (Fig. 7e).

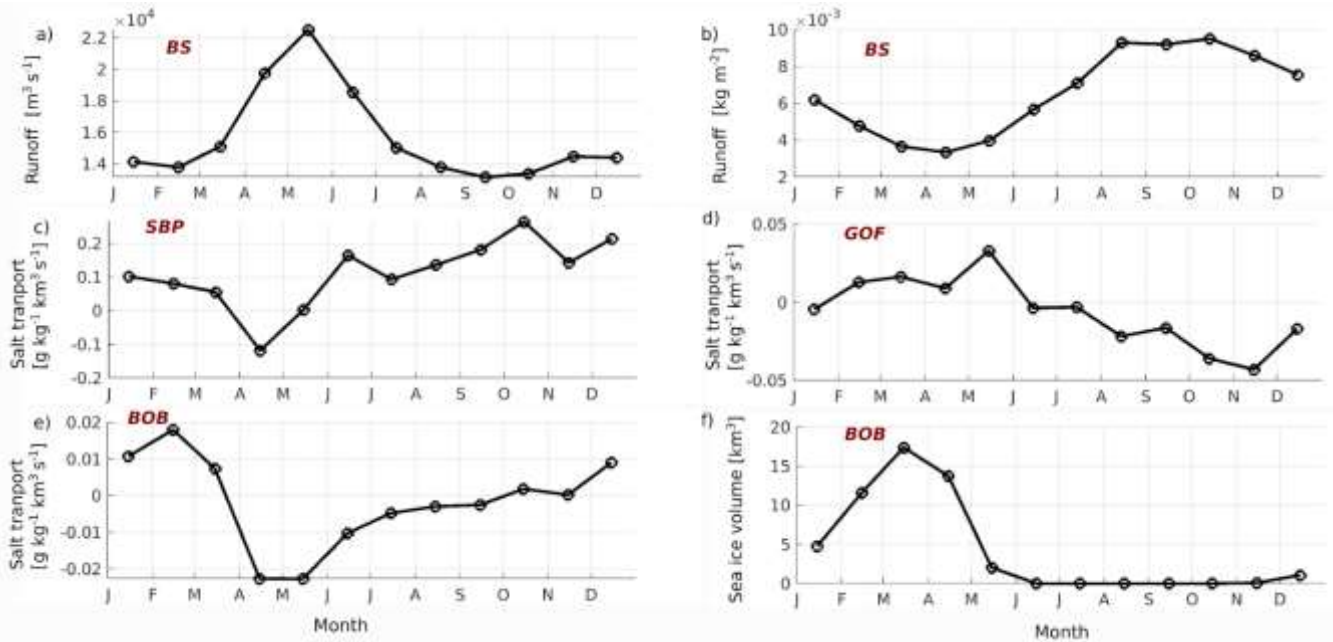

In the southern Baltic proper, FWC is low in winter and high in summer, (Fig. 6e), while in the Gulf of Finland the situation is the opposite. In the southern Baltic proper, large volume inflows of saline water take place in winter (Raudsepp et al., 2018; Lehmann and Post, 2015; Mohrholz, 2018), which reduces the FWC. In the Gulf of Finland the seasonal changes of FWC are
260 determined by intensive estuarine circulation in summer and the associated salt wedge dynamics (Maljutenko and Raudsepp, 2019). In winter, the salt wedge withdraws from the interior of the gulf, the mean salinity decreases and FWC increases. The formation and melting of the sea ice has a smaller effect on the FWC than in the Bothnian Bay. (Fig. 6f). Similarly, net salt transport to these basins is opposite in time (Fig. 7c.d). The seasonal course of FWC is almost absent in the northern Baltic Proper (Fig. 6c) where the influence from adjacent sub-basins, the southern Baltic Proper and the Gulf of Finland, which have
265 opposite FWC seasonality, could compensate for each other. In the Gulf of Riga, FWC is at its maximum in spring and decreases monotonically until winter (Fig. 6h). Surprisingly, the seasonal course of the FWC in the Kattegat (Fig. 6g) is like the seasonal course of the FWC in the Gulf of Riga (Fig. 6h). Dynamically, these two areas cannot be interlinked due to their geographical separation.

270

Figure 6. Seasonality of detrended FWC in the different Baltic Sea sub-basins. The abbreviations for the sub-basins are as follows: BS (Baltic Sea), NBP (Northern Baltic Proper), SBP (Southern Baltic Proper), KAT (Kattegat), BOB (Bay of Bothnia), BOS (Bothnian Sea), GOF (Gulf of Finland), GOR (Gulf of Riga). (data ref. 1, Table 1)

4 Discussion

280 A distinct feature of the Baltic Sea salinity evolution over the period 1993–2021 was the decreasing trend of the FWC in the southern Baltic Proper and increasing trend in the Bothnian Bay (Fig. 2). Overall, the FWC in the whole Baltic Sea had a statistically significant negative trend (Fig. 2). Salt transport to the Baltic Sea, net precipitation, and total river runoff to the sea (Supplement) did not explain the calculated trends. No steady increase of the salt transport to the Baltic Sea has been reported elsewhere, although deepwater salinity has increased in the Gotland Basin from 1993 to 2018 (Lehmann et al., 2022). The rate of $0.2\text{--}0.25 \text{ g kg}^{-1}$ per decade was estimated for the period 1979–2018 (Lehmann et al., 2022). In the Baltic Sea, there was no trend in net precipitation nor river runoff. Therefore, the decrease of FWC should be explained by accumulated salt flux from the North Sea to the Baltic Sea due to the Major Baltic Inflows (Mohrholz, 2018), large barotropic inflows (Lehmann et al., 2017), and smaller inflows of barotropic origin (Lehmann et al., 2022). Our estimations of the annual salt transport to the southern Baltic Proper did not show an increase of the salt flux (Supplement). In our reanalysis model data, the salt flux at the Danish straits could have large uncertainty due to relatively high salinity errors there (Appendix A). Inside the Baltic Sea area, as reanalysis model data have been calculated using assimilation of the observations, the estimates of FWC have low uncertainty due to low salinity errors (Appendix A).

285

290

Net precipitation and river runoff increased over the Bothnian Bay (Supplement), which contributed to the increase of the FWC (Fig. 2b). An increase of FWC was fastest at the surface of the bay and monotonically slowed down with depth (Fig. 4b). We would like to note that there are no studies that support or refute our findings on the increase of the FWC or the decrease of salinity in the Gulf of Bothnia.

The trends of FWC are present in our data, but this could be characteristic for the period of our study. Increase of the salinity in the central Baltic Proper since 1993 has been reported by Lehmann et al. (2022), which is consistent with our results about the decline of FWC. Going back further in time, the positive salinity trend becomes weaker (Lehmann et al., 2022) until it vanishes (Radtke et al., 2020). The study by Radtke et al. (2020) was prolonged into the past until 1850 but does not cover the last 15 years.

Many authors have reported dominant 30-year variability in mean, surface, and bottom salinity of the Baltic Sea as well as river runoff into the Baltic Sea and even salt transport across Darss sill (Kniebusch et al., 2019; Radtke et al., 2020; Lehmann et al., 2022). Our time series of 28 years are short to reveal 30-year variability in FWC, river runoff, or net precipitation with a statistical significance. Visual inspection of the time series of FWC does not hint to the presence of a 30-year cycle (Fig. 2). We admit the presence of decadal variability in the time series, which has been reported also by Lehmann et al. (2022). The trends and multi-scale variability of FWC are opposite in the Baltic Proper and in the Bothnian Bay (Fig. 2, Table 1). This raises the question: If FWC has opposite changes in the southern and northern Baltic Sea, how could changes in river runoff explain the opposite variability. Our analysis showed that there are multi-year periods when river runoff is in phase or out of phase with the FWC. An example of an in-phase period in the whole Baltic Sea is 1993–2009 and an out of phase period 2010–18 (Fig. 5a). In the Bothnian Bay, we mostly have river runoff and the FWC in phase and out of phase with salt transport.

Future climate model scenarios could provide insight into how combinations of different factors affect long term salinity changes in the Baltic Sea, although the uncertainties in the climate projections are high. Three main factors that affect salinity and FWC are the wind fields over the Baltic Sea region (Lass and Matthäus, 1996), river runoff to the Baltic Sea (Schinke and Matthäus, 1998), and global mean sea level rise (Meier et al., 2017, 2021). With increasing precipitation and river runoff, the salinity in the Baltic Sea decreases monotonically until the winter. In the Gulf of Riga, the seasonal course of the FWC is explained by the high river runoff in spring with a climatological monthly mean freshwater flux of $3400 \text{ m}^3/\text{s}$ in April (Raudsepp, 2001). (Saraiva et al., 2019). Mean sea level rise, in turn, tends to increase salinity because saltwater imports through the Danish straits are larger (Meier et al., 2017, 2021a). An increasing westerly wind could block the freshwater flow out of the Baltic Sea, causing reduced salt transport to the Baltic Sea (Meier and Kauker, 2003), but Schimanke et al. (2014) showed that the intensity and frequency of MBIs were projected to slightly increase due to changes in the wind fields. In summary, different factors affect salinity and FWC differently, so the observed effect cannot be explained in a simple way. For instance, Meier et al. (2021) stated that no changes in the Baltic Sea salinity were found because river runoff and sea level rise approximately compensated each other. Therefore, also in our study, we could not explain the trends and multidecadal variations, although we have considered main factors that affect the FWC of the Baltic Sea.

325

Surprisingly, the seasonal course of the FWC in the Kattegat is similar to the seasonal course of the FWC in the Gulf of Riga. Dynamically these two areas cannot be interlinked due to their geographical separation. Increase of FWC in the Kattegat in spring is the result of the outflow of low salinity water from the Baltic Sea manifested by low sea level in the Baltic Sea (Raudsepp et al., 1999). The seasonal course of the FWC of the entire Baltic Sea is shaped mainly by the seasonal course of the FWC in the southern Baltic Proper, but also has a contribution from the freshwater supply from the rivers in spring.

The long term tendencies show similar propagation with the natural estuarine exchange, where salty inflow in the sub-surface layer is gradually mixed in the upper layer which exhibits outflow towards the ocean. The elevated salinity inflows to the Baltic Sea reduce the FWC compared to the climatology in the deep layers of the southern Baltic Sea—this can be manifested from the negative trends below the permanent halocline in the southern and northern Baltic Proper (Fig. 4c,e). While salt inflows propagate to downstream basins (northern Baltic Proper, Gulf of Finland) and from the gradual mixing the surface layers should also exhibit negative tendencies, in case of the assumption that the freshwater inflow to the system does not change. These tendencies are either weak or non-existent in the Baltic Proper (Fig. 4), which suggest that the increased freshwater runoff and positive FWC tendencies in the northern sub-basins of the Baltic Sea have compensated corresponding trends of the FWC.

The definition of the FWC to the reference salinity determines the amount of freshwater necessary to bring the solution to the reference salinity (Boyer et al., 2007) therefore it characterises volumetric influence of freshwater toward the reference state. As such the FWC has a nonlinear relationship toward the change of the state (salinity) compared to its reference (climatology). In the Baltic Sea, where salinity climatology shows large gradients between sub-basins, such a relationship emphasises salinity changes in the southern (saltier) and northern (fresher) sub-basins differently.

Thus, the FWC could be a complementary proxy to characterise salinity stress to freshwater species adapting with the brackish water of the Baltic Sea (Vuorinen et al., 2015). And vice versa—the decrease of FWC which has nonlinear relationship to the unit changes of salinity could be an indicator for the alien species, which favour higher salinity conditions.

Quantitative estimation of the FWC budgets and their relationships toward the cumulative freshwater runoff and salty water inflows are out of the scope of the current study

355 **Conclusions**

The climatological FWC of the Baltic Sea show substantial Conclusion

360 Temporal variability both in time and of the FWC at different sub-regions. The timescales has an opposite pattern in the northern and southern sub-basins of the Baltic Sea show. The Gulf of Bothnia shows positive tendencies of FWC, while in the Baltic Proper mostly negative tendencies are can be witnessed. The total FWC of the Baltic Sea has decreased steadily with the rate of 23.9 km³/y. This decrease is⁻¹ over the years 1993–2021. There is no solid explanation for what caused by the increase of saline water it because different drivers could compensate each other to a certain extent.

365 Interannual variations of the FWC in the Bothnian Bay are supported by interannual variability of river runoff, net precipitation, and salt transport from the North Sea to the Baltic Sea. Seasonal Bothnian Sea. The latter being opposite to the changes of FWC. In the Bothnian Sea and Northern Baltic Proper, interannual variations of the FWC and net salt flux to the basins are opposite to each other. The changes in river runoff and net precipitation have a complex contribution to the changes of FWC. In the Southern Baltic Proper, the changes of FWC, river runoff, net precipitation, and net salt flux have rather complex relationships. A separate study is needed to understand the interplay of these factors, especially seeing as the variations of salt transport and FWC are opposite to each other from 1993 until 2010 but positively correlated thereafter.

370 The seasonal course of FWC in different sub-basins highlights the local dynamics and explains the FWC dynamics in relation to the local sources of freshwater. The relationship of the FWC to the salinity changes is nonlinear toward the corresponding reference state, therefore any of the extrapolations to new states i.e "ocean" or "lake" should be avoided. and salt transport through the sections that border the corresponding sub-basin. Seasonal changes of sea ice volume affect the seasonal cycle of the FWC in the Gulf of Bothnia.

375 Climate warming effect is manifested in reduced ice formation and increased net precipitation in the north-eastern sub-basins. This has led to the increase in FWC in the Bothnian Bay and eastern Gulf of Finland due to reduced retention of freshwater in ice and increase in runoff/net precipitation of freshwater. These FWC tendencies propagate towards the southern sub-basins according to the estuarine exchanges which results in compensation of FWC trends in surface layers there.

380 By taking into consideration the spatial and temporal tendencies of the FWC shown in each separate sub-basin, we can characterise the Baltic Sea as a typical estuarine system with a strengthening exchange flow in time. Geographically, the system spans from the Danish straits in the south to the Bothnian Bay in the north. The southern part corresponds to the estuary mouth, where saltwater transport from the ocean prevails and leads to a decrease in FWC. At the other end, the Bothnian Bay is a typical estuary head characterised by a significant influence of freshwater discharge, resulting in an increase in FWC over time. The northern Baltic Proper and the Bothnian Sea converge in the transitional zone between the saltwater-dominated region and the freshwater-dominated region. In terms of vertical distribution, the freshwater-influenced area extends towards

385 the estuary mouth in the upper layer, while the saltwater-dominated area extends towards the estuary head in the lower layer.

Moving eastward, the Gulf of Finland represents a branch of the main estuarine system and shares general characteristics of a transition zone, although it possesses its own unique estuarine structure and dynamics (Maljutenko and Raudsepp, 2019; Westerlund et al., 2019; Liblik et al., 2018).

390

Appendix A

We utilize a clustering method to assess the accuracy of the hydrodynamic model. This method provides insights into the overall model accuracy by clustering the errors. The clustering process employs the K-means algorithm, which is a form of unsupervised machine learning (Jain, 2010). The original description of this method can be found in the work of Raudsepp and Maljutenko (2022). In our assessment, all available data within the model domain and simulation period are included, even if the verification data is unevenly distributed or occasionally sparse. This approach allows us to evaluate the model quality at each specific location and time instance where measurements have been obtained.

395

The first step of the method is the formation of a two-dimensional error space of two simultaneously measured parameters. A two-dimensional error space (dS, dT) , where $dS=(S_{mod}-S_{obs})$ and $dT=(T_{mod}-T_{obs})$, of simultaneously measured temperature and salinity values was formed as the basis for the clustering. The dataset utilized in this validation study was obtained from the EMODNET dataset compiled by SMHI (SMHI, 2019). It comprises a total of 651,565 observations that align with the CMEMS Reanalysis simulation period, encompassing the years 1993 to 2021. We extracted the nearest model values from the reanalysis dataset for each observation.

400

The second step is the selection of the number of clusters. For simplicity, we preselected five clusters. The third step is to perform a K-means clustering of the 2-dimensional errors. The clustering is applied to the normalized errors. Normalization was done for temperature and salinity errors separately using corresponding standard deviations of the errors. The K-means algorithm finds the location of the centroids of a predefined number of clusters in the error space. The location of the centroids represents the bias of the set of errors for each cluster. The fourth step is calculation of statistical metrics of non-normalized clustered errors. Common statistics, like STD, RMSE, and correlation coefficient can be calculated for the parameters belonging to each cluster.

405

The fifth step is the analysis of spatio-temporal distributions of the errors belonging to different clusters. In the formation of the error space, we retained the coordinates of each error point $(dS, dT)(x, y)$, which enables us to map the errors belonging to each cluster back to the location where the measurements were performed. In order to do that, the model domain is divided into horizontal grid cells (i, j) of $1 \times 1 \text{ km}^2$ in size. Subsequently, the number of error points belonging to different clusters at each grid cell (i, j) is counted. The total number of error points belonging to the grid cell (i, j) is the sum of the points of each cluster. The share of error points in each grid cell belonging to cluster k is the ratio of the number of error points of cluster k and the total number of error points in each grid cell.

415

420 Figure A1 displays the results of the K-means clustering for non-normalized errors. Table A1 presents the corresponding
metrics. Within cluster $k=5$, the salinity and temperature values closely align with the observations, with a bias of $dS=-0.03$ g
 kg^{-1} and $dT=0.006$ °C, respectively. This cluster encompasses 77% of all data points. The points are distributed throughout the
entire Baltic Sea, with a dominant share exceeding 0.5 (Figure A1b). Clusters $k=3$ and $k=4$ exhibit relatively even spatial
distributions over the Baltic Sea, accounting for 8% and 7% of the points, respectively. These clusters are particularly
noteworthy due to their small salinity biases and variability, which are crucial for estimating the freshwater content (FWC)
directly impacted by salinity. Collectively, approximately 92% of all validation points exhibit relatively low salinity bias,
425 standard deviation (STD), and root mean square error (RMSE) (Table A1). Consequently, we anticipate that the model
reanalysis data provide sufficiently accurate information for calculating the FWC of the Baltic Sea.

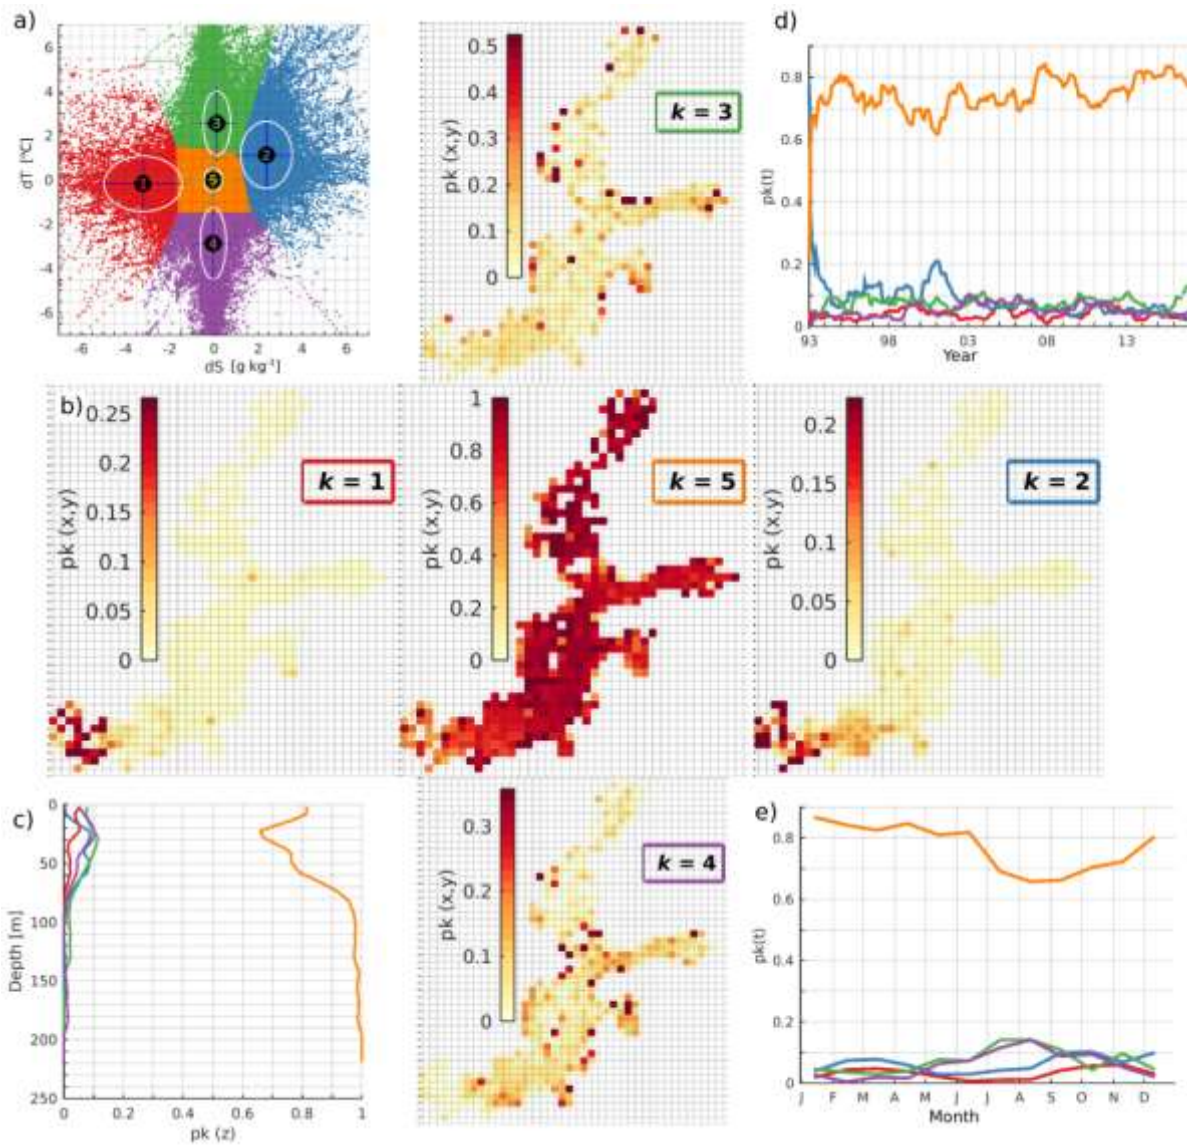

Figure A1. Distribution of normalized error clusters for $K=5$ (a). The spatial distribution (b, shaded sub-plots), vertical distribution (c), temporal distribution (d), and seasonal distribution (e) of the share of error points belonging to the five different clusters.

Appendix B

Mixing of two water masses (M_{ref}, M_f) with different salinities (S_{ref}, S_f) results in the mixture

440 ($M_{ref}+M_f$) with unknown salinity S

$$M_{ref}S_{ref} + M_fS_f = (M_{ref} + M_f)S \quad (B2.1)$$

If one of the water masses, M_f , is freshwater with $S_f=0$ and we assume that the densities of the water masses of different salinities have negligible difference, then (B2.1) simplifies to

$$V_{ref}S_{ref} = V_{ref}S + V_fS \quad (B2.2)$$

445 where V_{ref} and V_f are the volumes of reference water and freshwater, respectively. The formulation of Boyer et al (2007) for freshwater content (FWC) follows directly from (B2.2), where the volume of freshwater in the total volume of the mixture is

$$V_f = V_{ref} \left(\frac{S_{ref}-S}{S} \right) \quad (B2.3)$$

In the derivation of (B2.3), the volume of the mixture of two water masses is not limited.

450 The formulation (B2.3) answers the question of how much freshwater (V_f) is needed to dilute the water (V_{ref}) with salinity S_{ref} to the salinity S if $S < S_{ref}$. The volume of water with S will be ($V_{ref}+V_f$). If $S > S_{ref}$, then (B2.3) shows how much freshwater should be removed from the volume of water (V_{ref}) with the salinity S_{ref} to obtain water with the salinity S . In this case, the volume of resulting water with S will be ($V_{ref}-V_f$).

455 We would like to note that the relationship (B2.3) is not a linear relationship between salinity and V_f . There are straightforward conclusions that can be drawn from (B2.3). First, to obtain water with a salinity close to zero, infinite amount of freshwater is needed, independent of the S_{ref} .

$$\lim_{S \rightarrow 0} V_f = \infty$$

Second, no freshwater is needed to add to the water V_{ref} if the mixture has a salinity equal to S_{ref} . Third, if

$$\lim_{S \rightarrow \infty} V_f = -V_{ref},$$

which means that all water should be removed from the mixture.

460 In its practical application, the formulation (B2.3) means that fixed volume equal to V_{ref} was initially filled with the water of salinity S_{ref} . Then, V_f is the volume of freshwater that was needed to dilute the water to the observed salinity S . In this case, the volume of the mixture ($V_{ref}+V_f$) with salinity S is larger than the initial volume V_{ref} . This means that the amount of water in the mixture, V_f , with salinity S should be removed from the system after the mixing is complete. If $S > S_{ref}$, then $V_f < 0$, and this is the volume of freshwater that was removed from the system to obtain water with the salinity S . In such a case, the

465 volume of the mixture ($V_{ref}-V_f$) with salinity S is smaller than the initial volume V_{ref} . This means that the amount of water in the mixture, V_f with salinity S , should be added to the system.

In the natural system, water volume and salinity are conserved when volume and salt exchange with the outside system is allowed. First, we assume that the natural system is initially filled with water V_{ref} with salinity S_{ref} . Then, if at some time instant we observe that water salinity has decreased to S , so that $S < S_{ref}$, then V_f was added to the system either by river runoff or net

470 precipitation. (Without losing generality, we neglect the presence of ice in the system and variations of the water volume of the system.) At the same time, to fix the volume of the natural system, the amount of water V_f with salinity S must be removed from the system due to outflow through the open boundary, for instance. If water salinity has increased to S , so that $S > S_{ref}$, then the amount of freshwater V_f has been removed from the system either by evaporation or outflow through the open boundary. Simultaneously, to conserve the volume of water in the natural system, the amount of water V_f with salinity S must

475 be transported to the system due to inflow from the open boundary. We would like to note that in the current argumentation, the actual inflow/outflow volume and salt transport through the open boundary cannot be estimated from knowing the V_f .

The derivation of the formulation by Gustafsson and Stigebrandt (1996) is based on the conservation of salt in mixing of two water masses, i.e. (B2.1) and (B2.2) are valid. Additionally, the assumption behind their formulation is that the water volume of the mixture, $V = V_f + V_{ref}$, is known, while V_{ref} is an unknown volume. Thus, in addition to (B2.2), the unknown volume can

480 be expressed as

$$V_{ref} = V - V_f. \tag{B2.4}$$

Substituting (B2.4) into (B2.2), we can express FWC as

$$V_f = V \frac{(S_{ref}-S)}{S_{ref}}. \tag{B2.5}$$

The relationship between salinity and V_f is linear in (B2.5). Now for some conclusions that can be drawn from (B2.5). First,

485 if the salinity is $S=0$, then $V_f=V$, i.e. all water in the mixture is freshwater. Second, if $S=S_{ref}$, then $V_f=0$, i.e. there is no freshwater in the mixture. If $S > S_{ref}$, then we obtain that $V_f < 0$, which means that a fraction of the water in the mixture becomes negative. Therefore, in its initial applications (Gustafsson and Stigebrandt, 1996; Eilola and Stigebrandt, 1998; Winsor et al., 2001), the relationship (B2.5) is bounded to zero when $S > S_{ref}$. The argumentation about the dynamics of the freshwater content is not applicable to the formulation by Gustafsson and Stigebrandt (1996). In the applicability range $S \leq S_{ref}$, (B2.5) can be interpreted

490 as follows: initially, a fixed volume, V , is filled in with the water with salinity S_{ref} , then, the amount of water V_f with salinity S_{ref} is removed from the fixed volume and replaced with freshwater with volume V_f to obtain the mixture with salinity S . Technically, (B2.5) can also be used for the calculation of V_f if $S > S_{ref}$. We have calculated FWC for the whole Baltic Sea using (B2.3) and (B2.5) (Figure B1). The difference of the calculated FWC of the Baltic Sea is around 100 km^3 and rarely exceeds 200 km^3 , while the FWC anomaly of the Baltic Sea varies in the range of $\pm 1000 \text{ km}^3$. The estimates used by either formulation are between 10–20%. We would like to point out that FWC calculated by (B2.3) (Boyer et al., 2007) is always larger than FWC calculated by (B2.5) (Gustafsson and Stigebrandt, 1996)

$$\Delta FWC \equiv (B2.5) - (B2.3) = \frac{-(S - S_{ref})^2}{SS_{ref}} \quad (B2.6)$$

From (B2.6) we can see that the difference in FWC of two formulations increases with the increase of the difference between reference water salinity and the salinity of the mixture.

500 **Figure B1.** Time series of FWC in the Baltic Sea as calculated according to (B2.3) (black) and (B2.5) (violet) and difference between (B2.5) and (B2.3) (blue).

675 Table 2. Correlations table of the FWC between the sub-basins (Fig. 1) of the Baltic Sea (data ref. 1, Table 1).

680 **Figures**

685

Figure 1. Map of the Baltic Sea depth distribution (data ref. 1., Table 1). Boxes show the boundaries where the freshwater content for different sub-basin is calculated. The abbreviations which are used for the sub-basins are following: KAT—Kattegat, SBP—Southern Baltic Proper, NBP—Northern Baltic Proper, BOS—Bothnian Sea, BOB—Bay of Bothnia, GOF—Gulf of Finland, GOR, Gulf of Riga.

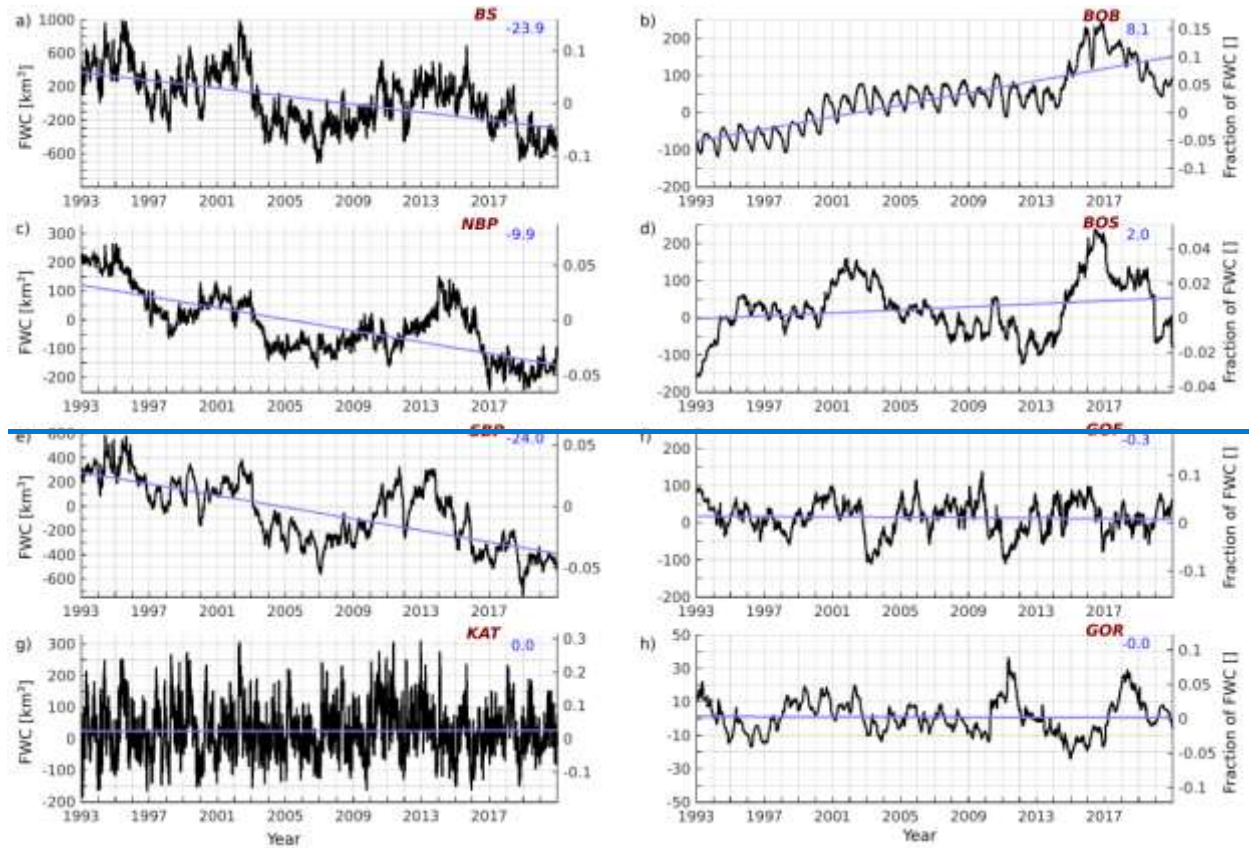

Figure 2. FWC timeseries in the Baltic Sea (a) and in different sub-basins (b-h). The trend of FWC in the corresponding basin is shown in the upper right corner (km^3 per year) and plot using the blue line (data ref 1, Table 1).

690

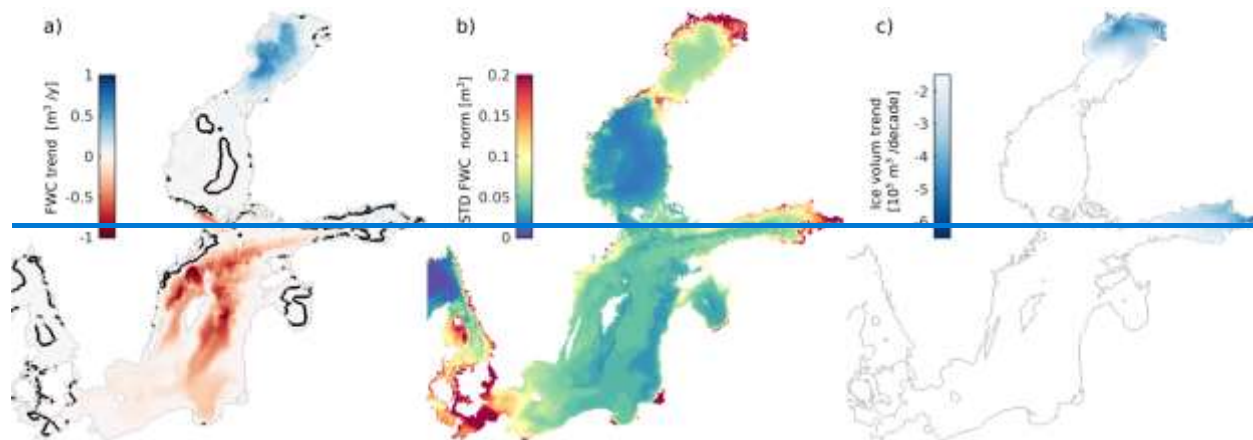

Figure 3. Trends (a) and depth-normalized standard deviation of the FWC (b). Trend of the ice volume (c). Data reference 1 (Table 1).

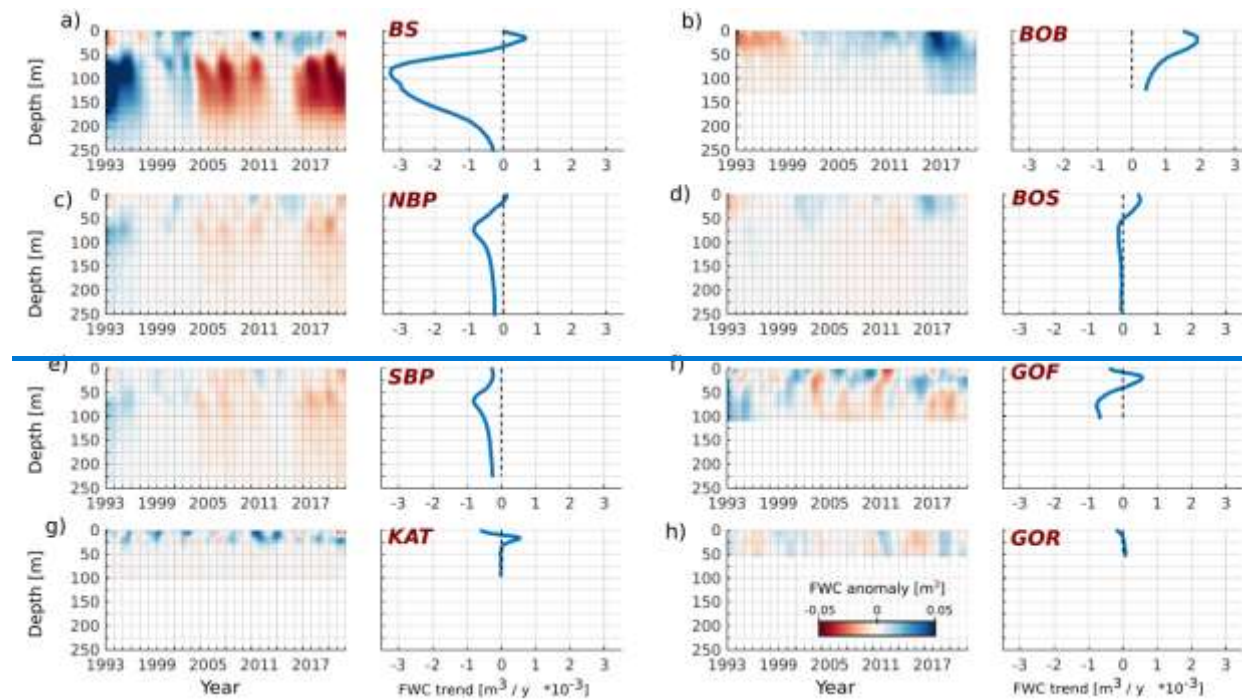

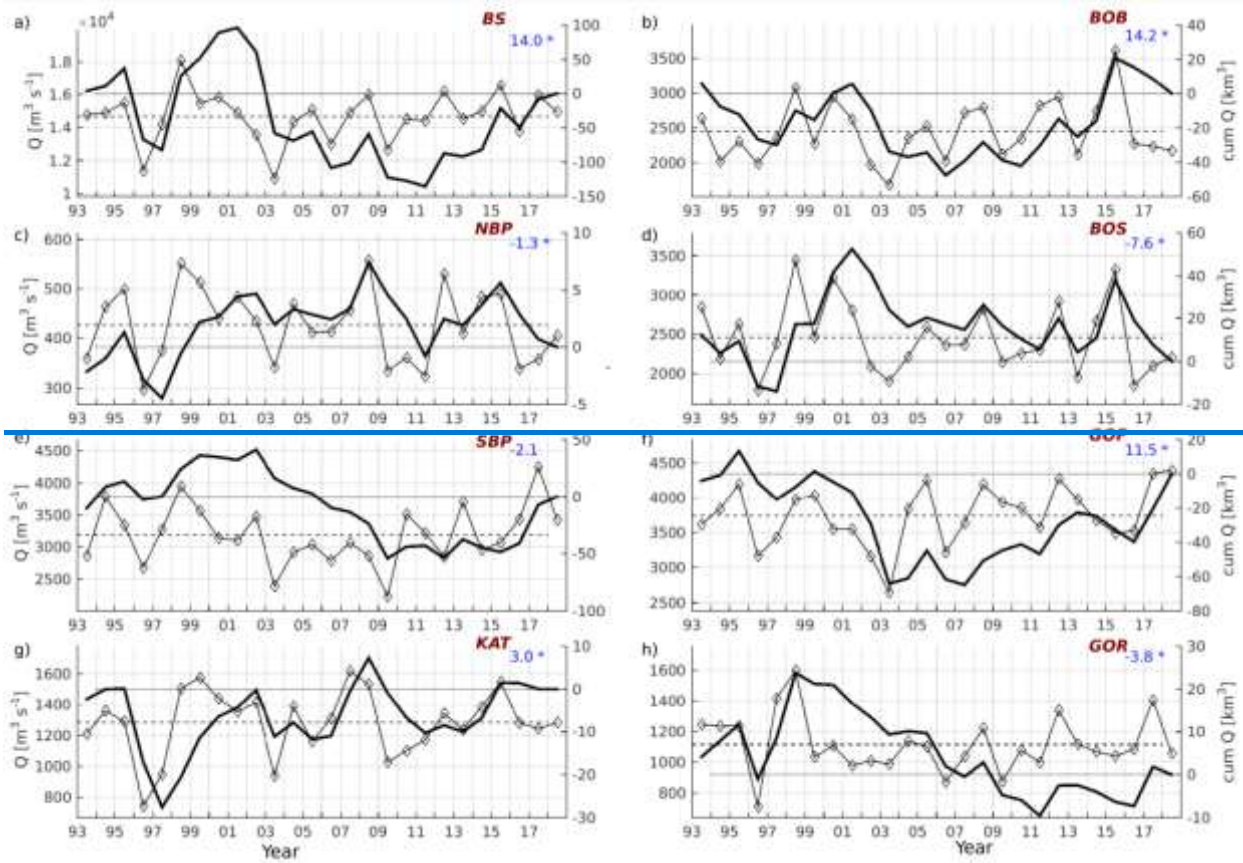

Figure 4. The vertical distribution of horizontal-mean FWC anomaly and corresponding trends for each Baltic Sea sub-basin (data ref. 1, Table 1).

700

Figure 5. The annual mean runoff (left axis, diamonds) and cumulative anomaly of the mean runoff (thick line). Trends of runoff shown in upper right corner ($\text{m}^3 \text{s}^{-1}$ per year). Asterisk marks the p-value > 0.05 . (data ref. 3, Table 1)

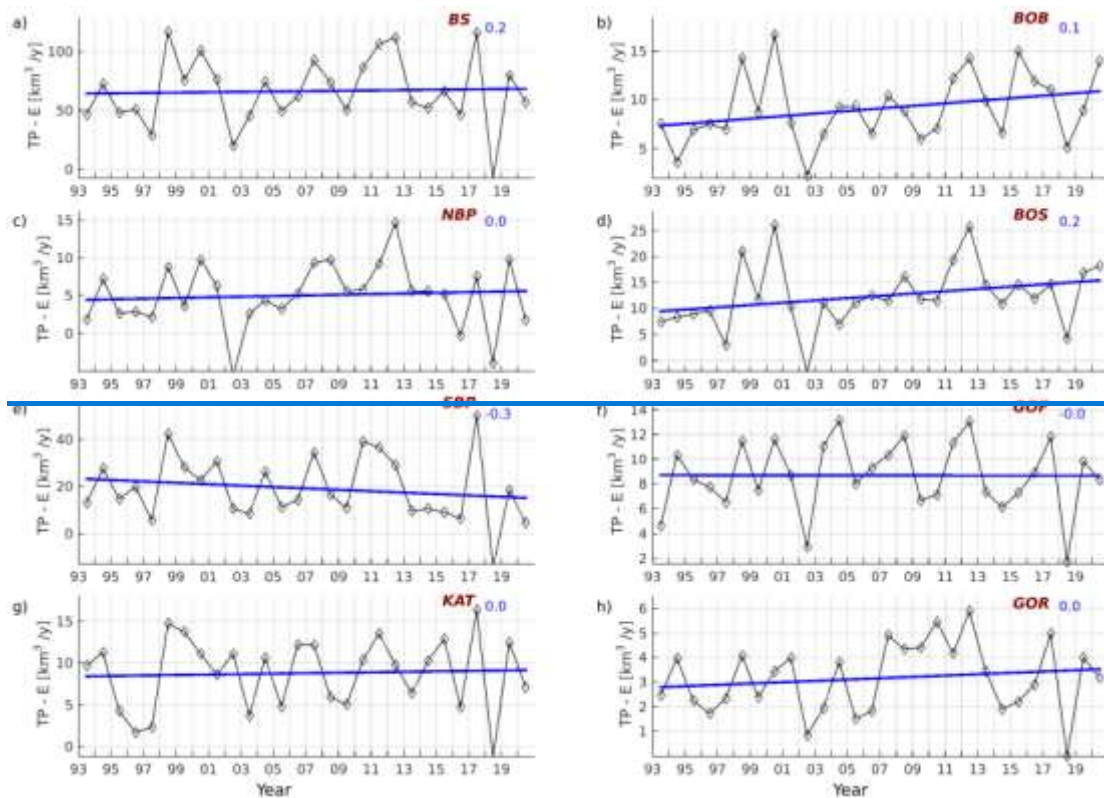

Figure 6. The annual net precipitation (precipitation–evaporation). Tendencies ($\text{km}^3\text{-year}^{-1}$ -per year) shown in upper corner and plot as blue line. (data ref. 2, Table 1)

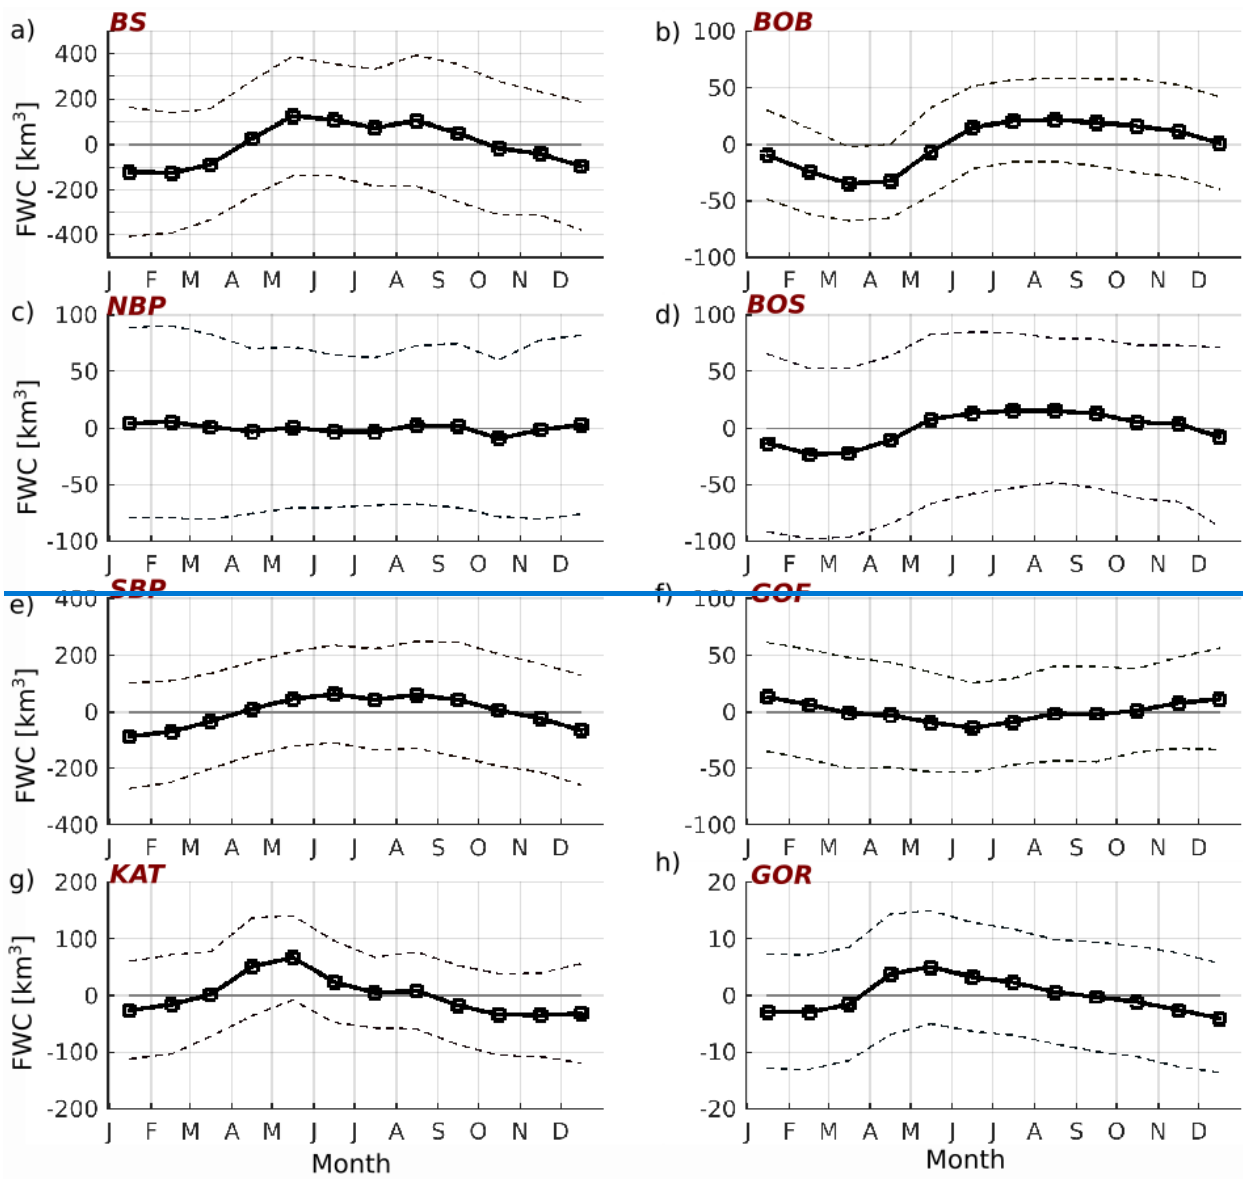

Figure 7. Seasonality of detrended FWC in the different Baltic Sea sub-basin. (data ref. 1, Table 1)
