Abstract. Oceanic exchanges across the Greenland-Scotland-Ridge (GSR) play a crucial role in shaping the Arctic climate and linking with the Atlantic Meridional Overturning Circulation. Most considered ocean reanalyses underestimate the observed 1993-2020 mean net inflow of warm and saline Atlantic Waters of 8.0 ± 0.5 Sv by up to 15%, with reanalyses at $1/4^\circ$ resolution additionally exhibiting larger biases in the single inflow branches compared to higher resolution products.

25 The underestimation of Atlantic Water inflow translates into a low bias in mean oceanic heat flux at the GSR of 5-22% in reanalyses compared to the observed value of 280 ± 18 TW. Interannual variations of reanalysis transports correlate reasonably well with observed transports in most branches crossing the GSR. Observations and reanalyses with data assimilation show a marked reduction of oceanic heat flux across the GSR of 4-9% (compared to 1993-2020 means) during a biennial (two-year-long) period centered on 2018, a record-low for several products. The anomaly was associated with a
30 temporary reduction of geostrophic Atlantic Water inflow through the Faroe-Shetland Branch and was augmented by anomalously cool temperatures of Atlantic waters arriving at the GSR. The latter is linked to a recent strengthening of the North Atlantic Subpolar Gyre and illustrates the interplay of interannual and decadal changes in modulating transports at the GSR.

35 **Short Summary.** This paper compares oceanic fluxes across the Greenland-Scotland-Ridge (GSR) from ocean reanalyses to largely independent observational data. Reanalyses tend to underestimate the inflow of warm waters of subtropical Atlantic origin and hence oceanic heat transport across the GSR. Investigation of a strong negative heat transport anomaly around 2018 highlights the interplay of variability on different time scales and the need for long-term monitoring of the GSR to detect forced climate signals.

45 **1 Introduction**

The Greenland-Scotland-Ridge (GSR), encompassing Denmark Strait, Iceland-Faroe (I-F) Ridge, Faroe-Shetland (F-S) Channel, and the European shelf, represents the main oceanic gateway to the so-called Arctic Mediterranean (the ocean bounded by the GSR, Davis Strait, and Bering Strait). Oceanic transports across the GSR play an important role for the Arctic and global climate systems. In the surface layer, the warm and saline Atlantic Water moves northward across the GSR and the light Polar Water flows southward mainly through the Denmark Strait. In the lower layer, the cold and dense water is transported southward at depth into the North Atlantic, contributing to the lower limb of the Atlantic Meridional Overturning Circulation (Hansen and Østerhus 2000; Buckley and Marshall 2016).

Transports across the GSR exhibit pronounced interannual variability, and thereby play an important role in modulating the heat budget of the Arctic Mediterranean (e.g., Muilwijk et al. 2018, Mayer et al. 2016, or Asbjørnsen et al. 2019). Specifically, the inflow of warm and saline Atlantic Water (AW) exhibits a strong co-variability with ocean heat content, especially of the AW layer of the Arctic Mediterranean (Mayer et al. 2022a). Tsubouchi et al. (2021), using observation-based oceanic transport data 1993-2016, revealed a step-change towards stronger oceanic heat transports (OHTs) across the GSR around 2002, suggesting an enhanced contribution of OHT to the observed warming of the Arctic Ocean. Mayer et al. (2022a) temporally extended the monitoring of OHT at the GSR using ocean reanalyses and found a pronounced reduction of OHT around 2018, which could not be verified with observational data at that time and the causes of which were not explored in detail.

Here, we use observational oceanic transport data at the boundaries of the Arctic Mediterranean updated to 2021 and an extended set of ocean reanalyses to explore the pronounced reduction of OHT in more detail, track it to the main contributing oceanic branch, and relate these changes to larger-scale climate variations on interannual and decadal time scales. An additional aspect of this study is a more detailed validation of reanalysis-based oceanic transports at the GSR at the scale of single branches, to further build trust in the usefulness of these products for monitoring Arctic climate and its oceanic drivers.

2 Data and methods

We use monthly data from a comprehensive set of ocean reanalyses to compute oceanic transports across GSR, Davis Strait, and Bering Strait. The latter two straits are calculated to close the volume budget and obtain unambiguous net heat transport into the Arctic Mediterranean (Schauer et al. 2009). Inflow (positive) has been defined as positive towards the Arctic Mediterranean. The employed products are an updated ensemble based on the Copernicus Marine Environment Monitoring Service Global Reanalysis Ensemble Product (CMEMS GREPv2, product ref 1), consisting of ORAS5, CGLORS,

75 GLORYS2V4, and GloRanV14 [an improvement of GloSea5 (MacLachlan et al., 2015), also known as the FOAM product;
product ref 6]. These are all run at $1/4^\circ$ horizontal resolution with 75 vertical levels and use atmospheric forcing from ERA-
Interim (Dee et al. 2011). The ensemble is complemented with GLORYS12 version 1 (product ref 2), a reanalysis at $1/12^\circ$
horizontal resolution with 50 vertical levels driven by ERA-Interim atmospheric forcing. Furthermore, two hindcast ocean
80 simulations (i.e., with no data assimilation) at $1/4^\circ$ horizontal resolution with 50 vertical levels (GLOB4) and $1/16^\circ$ horizontal
resolution and 98 vertical levels (GLOB16; Iovino et al., 2016) driven by JRA55-do (Tsuji no et al., 2018) are employed to
investigate the impact of resolution on oceanic volume fluxes. Heat transports from GLOB4 and GLOB16 are not assessed
as these are biased due to their setup as forced runs without data assimilation. Transports are computed on the native grid
through line integrals similar to Pietschnig et al. (2018).

Observational mass-consistent estimates of oceanic transports (product ref 3) are updated to July 2021 following Tsubouchi
85 et al. (2021; i.e., using the same strategy to infill data gaps, uncertainty estimation, and box inverse model to close the
volume budget). Temporal coverage and references for the single observational estimates used as input are provided in the
data table (Table 1). Surface freshwater inputs by river discharge and precipitation minus evaporation for 1993-2021 as input
to the box inverse model are based on Winkelbauer et al. (2022). The used reanalyses assimilate temperature and salinity
profiles available from data bases such as Hadley EN4 (Good et al. 2013), which according to our investigations include
90 only a small subset of the mooring data used for our observational transport estimates. Currents are generally not assimilated
in ocean reanalyses. Hence, the observation-based volume fluxes represent fully and temperature fluxes largely independent
validation data.

We note that quantification methods of oceanic transports in reanalyses and observations are fundamentally different, which
needs to be kept in mind when intercomparing. The reanalysis-based estimate is based on surface to bottom, coast to coast
95 temperature and velocity sections across the Arctic Mediterranean. This ensures conservation of volume and avoids
projection of potentially biased positioning of currents in the reanalyses onto the transport estimates. The observational
estimate is based on the sum of 11 major ocean current transport estimates that is categorized into three major water masses
– AW, PW and OW (Tsubouchi et al., 2021). An assumption is that the 11 major ocean currents represent well the major
water mass exchanges across the Arctic Mediterranean. This means it is important that no recirculation, e.g. of AW waters,
100 remains unobserved, as this would introduce biases to the observational estimate. This assumption has been assessed and
confirmed many times over the last two decades from establishment of sustained hydrographic sections in GSR in the
1990ies (e.g. Dickson et al., 2008) to recent oceanographic surveys to capture ocean circulation in GSR for AW (e.g. Berx et
al., 2013, Hansen et al., 2017, Rossby et al., 2018, Jónsson and Valdimarsson, 2012) and OW (Hansen et al., 2018). We also
note that remaining uncertainties arising from potential undersampling are taken into account in the observational estimate
105 obtained through the inverse model. For reference, Fig. 1 shows pathways of major flows across the GSR as well as
locations of considered oceanic moorings and the sections used for evaluation of reanalyses.

As in Mayer et al. (2022a), we assume total uncertainties of monthly mean observations (provided in Tsubouchi et. al 2021) to consist of roughly half systematic and half random errors, i.e. the two contributions are the total uncertainty reduced by a factor of $\frac{1}{\sqrt{2}}$, respectively. Consequently, the contribution of random errors to uncertainties of long-term mean observational estimates are further reduced by a factor of $\frac{1}{\sqrt{N}}$, where N is the number of years, and deseasonalized anomalies only include the random errors.

Transported water masses at the GSR are decomposed into Atlantic (AW), Polar (PW), and Overflow Waters (OW), largely following Eldevik et al. (2009). PW is defined as $T < 4^\circ\text{C}$ and $\sigma_\theta < 27.7\text{kg/m}^3$. OW is defined as $\sigma_\theta > 27.8\text{kg/m}^3$. The rest (i.e., waters with $\sigma_\theta < 27.8\text{kg/m}^3$ with PW taken out) is considered AW. Note, these definitions have been revised from Mayer et al. (2022a). Water mass decomposition is performed each month based on the monthly temperature and salinity fields in the reanalyses. These definitions are similar to those used for observational products (see references for more details).

We additionally use sea level anomaly (SLA) data provided through CMEMS (product ref 4) for investigating drivers of observed OHT anomalies. The global mean SLA trend is removed before computation of the presented diagnostics.

Deseasonalized anomalies are based on the 1993-2019 climatologies, i.e. the period for which all data are available. Anomaly time series have a 12-monthly temporal smoother applied to emphasize interannual variations. Confidence levels (95% is set as threshold for significance testing) for temporal correlations take auto-correlation of the involved time series into account (see Oort and Yienger 1996).

3 Results

3.1 General evaluation of transports of water masses across GSR

Figure 2 presents mean annual cycles and anomaly time series of relevant oceanic transport quantities at the GSR. It is complemented with long-term averages shown in Table 2 (volume fluxes) and 3 (heat fluxes). Observations show seasonally varying AW inflow across the GSR (8.0 ± 0.5 Sv; mean \pm standard deviation of the mean reported throughout unless explicitly stated) with a maximum in December and minimum in June-July (Fig. 2a). The AW inflow is largely balanced by PW (Fig. 2c; -1.8 ± 0.7 Sv) and OW (Fig. 2b; -5.6 ± 0.3 Sv) outflow, yielding a relatively small net volume flux across the GSR of 0.7 Sv (balanced by flows through Bering and Davis Straits). The PW outflow exhibits an annual cycle balancing the AW inflow (i.e., maximum outflow in boreal winter), while the OW exchange is more stable throughout the year (i.e., small annual cycle).

All reanalyses but one (CGLORS) underestimate AW inflow across the GSR when compared to observations, but the shape of the annual cycle of all estimates is in good agreement with observations. The AW net flow from high-resolution products does not stand out compared to the $1/4^\circ$ products and is close to the GREP mean. Agreement is also good for the PW outflow, where all products show the observed seasonal maximum flow in boreal winter. The range of reanalysis-based estimates is large in a relative sense, with the observations lying in the middle of the range. There is less coherence across products concerning the OW transports. GLORYS12, GLORYS2V4, and CGLORS are close to observations, with rather persistent overflow on the order of -5.4 Sv, with seasonal variations that agree with the observations. Other products tend to have overflows that are too weak (most notably ORAS5), and some also exhibit biases in the representation of the annual cycle (e.g., GloRanV14).

Table 2 additionally includes long-term average volume fluxes in the main AW inflow branches (North Icelandic Irminger Current (NIIC), I-F branch, F-S branch, and the European Shelf). The reanalysis-based estimates agree generally well with observations. The main discrepancy is the underestimation of I-F inflow and overestimation of F-S inflow by all GREP reanalyses, while the high-resolution products GLORYS12 and GLOB16 are in much better agreement with observations. Direct comparison of GLOB16 to GLOB4 confirms that overestimation of F-S volume flux is reduced when going from $1/4^\circ$ to $1/16^\circ$ resolution. This suggests that increased resolution, along with more realistic bathymetry, improves representation of inflow pathways in the reanalyses. We also note that temporal anomaly correlations with observed I-F volume fluxes are low (Pearson correlation coefficients r range in -0.03 to 0.26 and are statistically insignificant) for all reanalyses but are substantially higher for F-S volume fluxes (r ranges in 0.30 to 0.71 , statistically significant for all products with data assimilation).

Fig. 2d shows the mean annual cycle of heat flux across the GSR, i.e. the sum of sensible heat transported by all waters crossing the GSR. The mean annual cycle of GSR heat fluxes generally follows that of AW volume fluxes, with a minimum between boreal spring/early summer and a maximum in fall/early winter. Seasonal minima and maxima in GSR heat flux co-occur with those of AW volume flux, i.e. seasonal variations in heat flux are largely volume-flux-driven and the seasonal cycle in volume-weighted temperatures is in phase.

Since net volume flux across the GSR is small, the ambiguity arising from the choice of reference temperature can be considered small as well. However, for the long-term averages we focus on net heat transport into the Arctic Mediterranean, i.e. the sum of heat fluxes across the GSR, plus those through Bering and Davis Straits. Values in Table 3 show that all reanalyses exhibit lower net heat transport (by $\sim 16\%$ for the GREP mean of 256 ± 19 TW) than that observed (306 ± 19 TW; 311 ± 20 TW when including sea ice). GLORYS12 exhibits a mean net heat flux similar to the GREP mean, but we note that all GREP reanalyses have too strong AW influx in the F-S branch (Table 2), where climatologically the warmest waters cross the GSR and thus enhance the heat flux in those products for the wrong reason.

165 The net heat transport is clearly related with the strength of AW inflow, but even CGLORS with a higher AW mean volume
flux (8.3Sv) than observations has a negative net heat flux bias. The reason is that all reanalyses exhibit a warm bias in
outflowing OW (not shown) and a cold bias in Davis Strait inflow (see Pietschnig et al. 2018). Based on Mayer et al. (2022a)
and taking account of oceanic storage, the energy-budget-based estimate of the net heat boundary transport suggests even
170 higher values (~348 TW) than observations. This inferred value appears high, but we note that this indirect approach has
been applied successfully to infer observation-based oceanic transports in the North Atlantic (Trenberth and Fasullo 2017,
Liu et al. 2020, Mayer et al. 2022b) and the central Arctic (Mayer et al. 2019), and hence is deemed credible. At least, this
estimate adds confidence that the observational estimate of oceanic heat transport is not biased high. Table 3 also confirms
that long-term averages for heat flux across the GSR are qualitatively very similar to the net heat transport, i.e., heat fluxes
across the GSR are the dominant contributor to oceanic heat transport into the Arctic Mediterranean.

175 Fig. 2e shows deseasonalized anomalies of AW volume flux, with a 12-monthly smoother applied to emphasize interannual
variability. Typical variability is similar across observations (temporal standard deviation $\sigma = 0.35$ Sv) and reanalyses (σ
ranges in 0.22 to 0.47 Sv). Temporal correlations between reanalysed and observed AW inflow anomalies are moderately
high (r ranges in 0.39 and 0.60, see legend of the plot for values, and is statistically significant for all products).

Fig. 2f shows anomalies of total oceanic heat flux across the GSR, which show similar variability as AW volume flux, i.e.
180 the strength of AW inflow not only modulates the seasonal cycle of the total GSR heat flux, but also its interannual
variations (r ranges in 0.86 to 0.91). GSR total heat flux from reanalyses is in slightly better agreement with observations
than AW volume fluxes (r ranges in 0.51 and 0.63, see legend of plot for values, and is statistically significant for all
products). Fig. 2f also shows a prominent negative heat flux anomaly centered around the year 2018, which has already been
noted by Mayer et al. (2022a) for net heat transport into the Arctic Mediterranean.

185

3.2 Spatial structure of the 2017/07-2019/06 transport anomaly

To set the scene for further investigation, we present climatological temperatures and currents at the GSR based on
GLORYS12 in Fig. 3a and b, respectively. Comparison with analogous figures based on the GREP [shown in Mayer et al.
(2022a)] allows to appreciate the benefits of increased resolution ($1/12^\circ$ vs $1/4^\circ$ resolution), including a more distinct
190 representation of inflow and outflow branches and a spatially more variable bathymetry, especially in the I-F branch.

Next, we investigate in more detail the recent reduction of AW volume and GSR heat fluxes. This is most prominent in the
biennial (two-year-long) signal of average anomalies in 2017/07-2019/06. Fig. 3c shows that, during this period, strong
warm anomalies were present over 0-400m depth in eastern Denmark Strait and warm anomalies are also seen in the F-S
branch. The latter suggests a temporary deepening of the AW layer. Velocity anomalies for the 2017/07-2019/06 period (Fig.

195 3d) suggest that the positive temperature anomalies in eastern Denmark Strait are driven by enhanced NIIC transports. The strongest and deepest velocity anomaly in 2017/07-2019/06 is located in the eastern part of the F-S branch, where reduced inflow is present from the surface down to the interface at ~600m, and hence we focus on this branch next. Negative anomalies are also seen in the overflow from 600m to 1000m depth. There is some compensation by positive velocity anomalies in western F-S (meaning reduced southward flow there), but the effect of the eastern F-S anomaly dominates, and
200 the net F-S volume flux anomaly was clearly reduced during this period (see below). We note that these main features are similar also in anomaly sections based on the GREP ensemble mean (not shown).

Observations and all reanalyses show large negative F-S volume inflow anomalies of $-0.61\text{Sv}/-0.56\text{Sv}/-0.34\text{Sv}/-0.24\text{Sv}$ in observations/GREP_mean/GLORYS12/GLOB16, respectively, during 2017/07-2019/06 (Fig. 3e). In four out of seven datasets, this is the overall biennial minimum of the 1993-2021 record (not shown). The total AW volume flux anomaly for
205 that period was $-0.24\text{Sv}/-0.53\text{Sv}/-0.37\text{Sv}/+0.08\text{Sv}$ in observations/GREP_mean/GLORYS12/GLOB16, respectively. Thus, F-S volume flux anomalies were partly compensated by other AW branches, with no very clear signal in any of them (not shown). Only GLOB16 exhibits a positive AW volume flux anomaly during that period, which appears to be related to a shift towards generally higher AW volume flux around 2016 (see Fig. 2e). This is not seen in any of the other products.

Temperature transport anomalies in the F-S branch are strongly correlated with volume flux anomalies (compare Fig. 3e and
210 f), and there is a clear reduction of F-S branch temperature flux in 2017/07-2019/06 by $-21.9\text{TW}/-24.1\text{TW}/-16.1\text{TW}$ in observations/GREP_mean/GLORYS12. The contribution of temperature anomalies in the F-S Channel during that time was small, with biennial anomalies of observed volume-weighted temperatures between -0.2 and -0.1 K (similar for all products). The total AW heat flux anomaly for 2017/07-2019/06 was $-11.0\text{TW}/-22.5\text{TW}/-19.4\text{TW}$ in observations/GREP_mean/GLORYS12. Thus, the reduction of GSR heat transports during that period was mainly driven by
215 a reduction of volume inflow through the F-S branch. It was only partly offset by compensating transport anomalies in other branches. Very similar biennial heat transport anomalies for the total GSR ($-11.1\text{TW}/-20.9\text{TW}/-19.3\text{TW}$ for observations/GREP_mean/GLORYS12) confirm AW as the main driver of heat flux variability across the GSR.

3.3 Relationships between sea level and AW inflow

220 For a better understanding of mechanisms contributing to the GSR transport anomaly around 2018, we first consider basic statistical relationships between SLA and oceanic quantities. We find a statistically significant temporal correlation of the zonal SLA gradient at GSR with observed AW volume flux anomalies (Fig. 4a), which is plausible in terms of geostrophic balance. The correlation pattern looks very similar when performed with the F-S branch volume flux alone (not shown). The pattern of temporal correlation between the SLA field and observed anomalies of volume-weighted temperature of AW

225 transports (Fig. 4b) is distinct from the relationship with AW volume flux (compare Fig. 4a). It emphasizes SLA in the North Atlantic Subpolar Gyre (SPG), with higher SLA in the SPG (i.e., a weaker gyre) associated with higher volume-weighted temperature, and vice versa. Although correlations are high (r up to 0.69) in the SPG region, they are not statistically significant. The cause may be the low number of degrees of freedom, as the SLA in the SPG exhibits high temporal auto-correlation (see Fig. 4d discussed below).

230 Actual SLA anomalies averaged over 2017/07-2019/06 (Fig. 4c) indicate a weakened zonal SLA gradient at the GSR, albeit not very strongly pronounced, and anomalously low SLA in the SPG region. According to the correlation patterns discussed above, these two features suggest reduced AW volume flux (as suggested by patterns in Fig. 4a) and anomalously low AW volume-weighted temperatures (as suggested by patterns in Fig. 4b). We also note the positive SLA anomalies north of the GSR with a maximum in the central Nordic Seas.

235 To put these results in context, we define two SLA-based indices (shown in Fig. 4d) from the correlation patterns found in Figs. 3a and b. The similarity of correlations in Fig. 4a to the correlation between total OHT at the GSR and SLA shown in Mayer et al. (2022a) reinforces use of their gradient-based index (i.e., standardized SLA difference between 58-60 N / 2-0 W and 63-67 N / 20-15 W). This index is correlated with AW volume flux anomalies ($r=0.62$ for observed transports and ranges in 0.47 to 0.70 for reanalyses - statistically significant in all cases). The second index uses spatial SLA averages in the North

240 Atlantic region (55 - 60 N and 40 - 15 W) as an inverse proxy of SPG strength. This index is correlated with anomalies of volume-weighted temperatures of AW transports. The two indices in Fig. 4d show different characteristics, with the SPG index varying on decadal time scales, while the gradient index shows stronger interannual variations. The SPG index has been negative after ~2014, which suggests a strong SPG and lower inflow temperatures in recent years, in agreement with results by Hátún and Chafik (2018). This SPG index exhibits two minima during the 2017/07-2019/06 period, although not
245 extreme relative to the entire time series.

Fig. 4e shows volume-weighted temperatures of AW waters from different products and confirms their overall decrease in recent years. Comparison with the SPG index in Fig. 4d suggests a generally delayed response of volume-weighted temperature in Atlantic inflow water at the GSR to SPG strength. Lagged correlation analysis indeed suggests positive correlations peaking (at values around 0.3 to 0.5, depending on data sets) when temperatures are lagging the SPG index ~2-3
250 years (not shown), but correlations are not significant due to the high auto-correlation of time series.

4 Conclusions

Reanalysis-based oceanic transports show generally good agreement with observations on the scale of single branches of the GSR, both in terms of mean and variability of volume and heat fluxes. There is some indication that the higher resolution

255 products have a better representation of AW inflow in the I-F and F-S branches. All considered products underestimate net
heat flux into the Arctic Mediterranean. The magnitude of the low bias is correlated with the strength of AW volume flux but
a warm bias in OW and cold bias in Davis Strait inflow further add to the found net heat flux bias. We reiterate that
reanalysis-based and observational transport estimates are obtained in different ways (closed line integrations versus
260 measurements from 11 branches with an inverse model applied) but, as elaborated in section 2, we deem this a fair and
robust approach for an intercomparison. The energy-budget-based estimate from Mayer et al. (2022a) suggests even higher
net heat flux than oceanic observations, which confirms the underestimation of heat transports by the ocean reanalyses. A
much smaller discrepancy was found in an analogous comparison of observed oceanic transports into the central Arctic and
an energy-budget-based estimate (Mayer et al. 2019), potentially reflecting the different observational strategies in Fram
Strait and Barents Sea Opening compared to the GSR (see, e.g., Dickson et al. 2008) or potential biases of the employed
265 energy budget fields over the Nordic Seas.

All reanalyses with data assimilation and observations show a pronounced reduction of OHT during the two-year period
2017/07-2019/06, with some recovery after that. Comparison of observed SLA patterns during this period with statistical
relationships between SLA and oceanic transports suggests that this reduction arose from a combination of interannual (i.e.,
reduced zonal SLA gradient at the GSR) and decadal scale changes (i.e., strong SPG in recent years). Another potential
270 factor contributing to the OHT reduction during 2017/07-2019/06 may have been the positive SLA anomalies centred in the
Nordic Seas (Fig. 4c), which Chatterjee et al. (2018) have related to a weakened gyre circulation in the Nordic Seas and may
have contributed to the weakened AW inflow as well.

Our results also reveal a delayed response of AW inflow temperatures to SPG strength. This is consistent with earlier studies
finding anti-correlation between SPG strength and GSR heat transport (Häkkinen et al., 2011; Hátún et al., 2005).
275 Specifically, the generally weaker SPG during ~1997 and ~2014 (with more pronounced minima in 1997-98, 2010-11, and
2003-06, see Hátún and Chafik, 2018) was associated with warm inflow temperatures and stronger OHT after 2001
(Tsubouchi et al. 2021). After that, the SPG strengthened and the inflow temperatures declined, which is also consistent with
generally reduced oceanic heat transports in recent years.

The presented results indicate that decadal predictions of the SPG strength, which have been shown to exhibit skill (e.g.,
280 Robson et al. 2018 and Borchert et al. 2021), may also allow to infer near-term trends in OHT across the GSR. Another
implication is that the strong interannual-to-decadal variability of OHT across the GSR hampers detection of longer-term
(forced and unforced) trends in observed OHT, an aspect in which climate simulations show large spread (Burgard and Notz
2017). Continued in-situ monitoring of OHT, complemented with reanalysis efforts, is thus needed to provide
observationally constrained time series of sufficient length for climate model validation.

405 **Table 2. Long-term mean of volume flux in different water masses and branches across GSR. Observational European Shelf volume fluxes are based on Østerhus et al. (2019). All values are based on 1993-2020 (since observational data does not cover 2021 completely) data, except for GLOB16 and GLOB4 (based on 1993-2019 data).**

	GSR total	Arctic Mediterranean
observations	280±18	306±19
GREP mean	243±21	256±19
ORAS5	219	239
CGLORS	265	276
GLORYS2V4	234	242
GloRanV14	255	269
GLORYS12	243	252
Energy-budget based	-	348

410 **Table 3. Long-term mean of total heat flux across GSR and into the Arctic Mediterranean (=total GSR transports plus Bering and Davis Strait transports). The energy-budget-based transport estimate is taken from Mayer et al. (2022a) and by definition can only be provided for a closed area like the Arctic Mediterranean. All values are based on 1993-2020 data.**

415

Figures

420 **Fig. 1.** Map of the Greenland-Scotland Ridge region, schematically depicting shallow shelf and deep water, major AW inflow (red arrows) and OW outflow (blue arrows) branches, location of oceanic moorings used for deriving the observation-based transport estimates (yellow bars), and the section used for computation of transports from ocean reanalyses (dashed green line). Adapted from OceanSITES (<http://www.oceansites.org/tma/gsr.html>, Fig. 1).

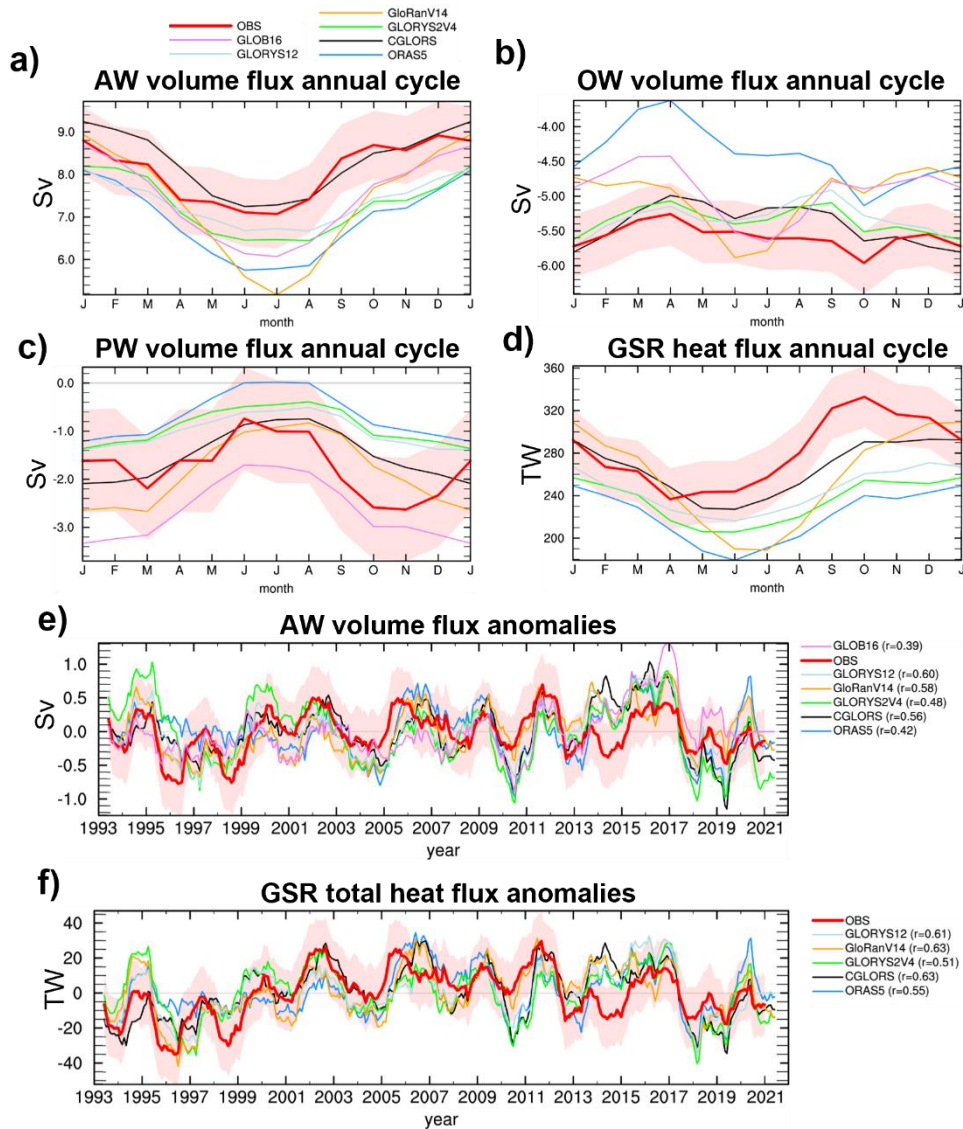

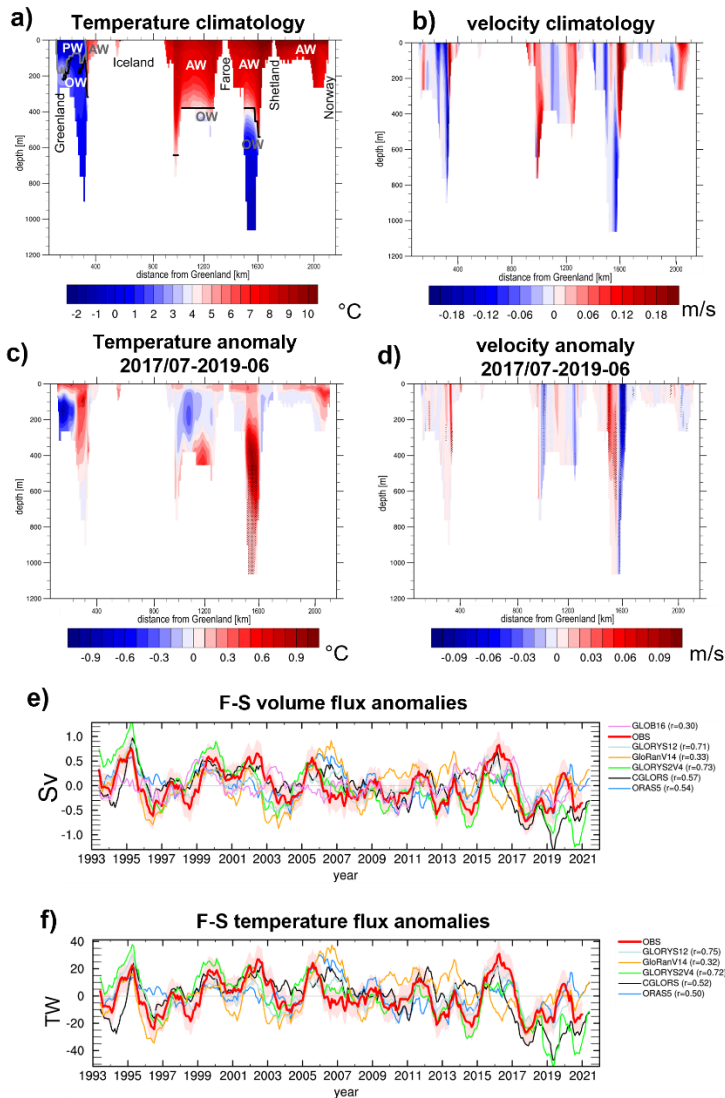

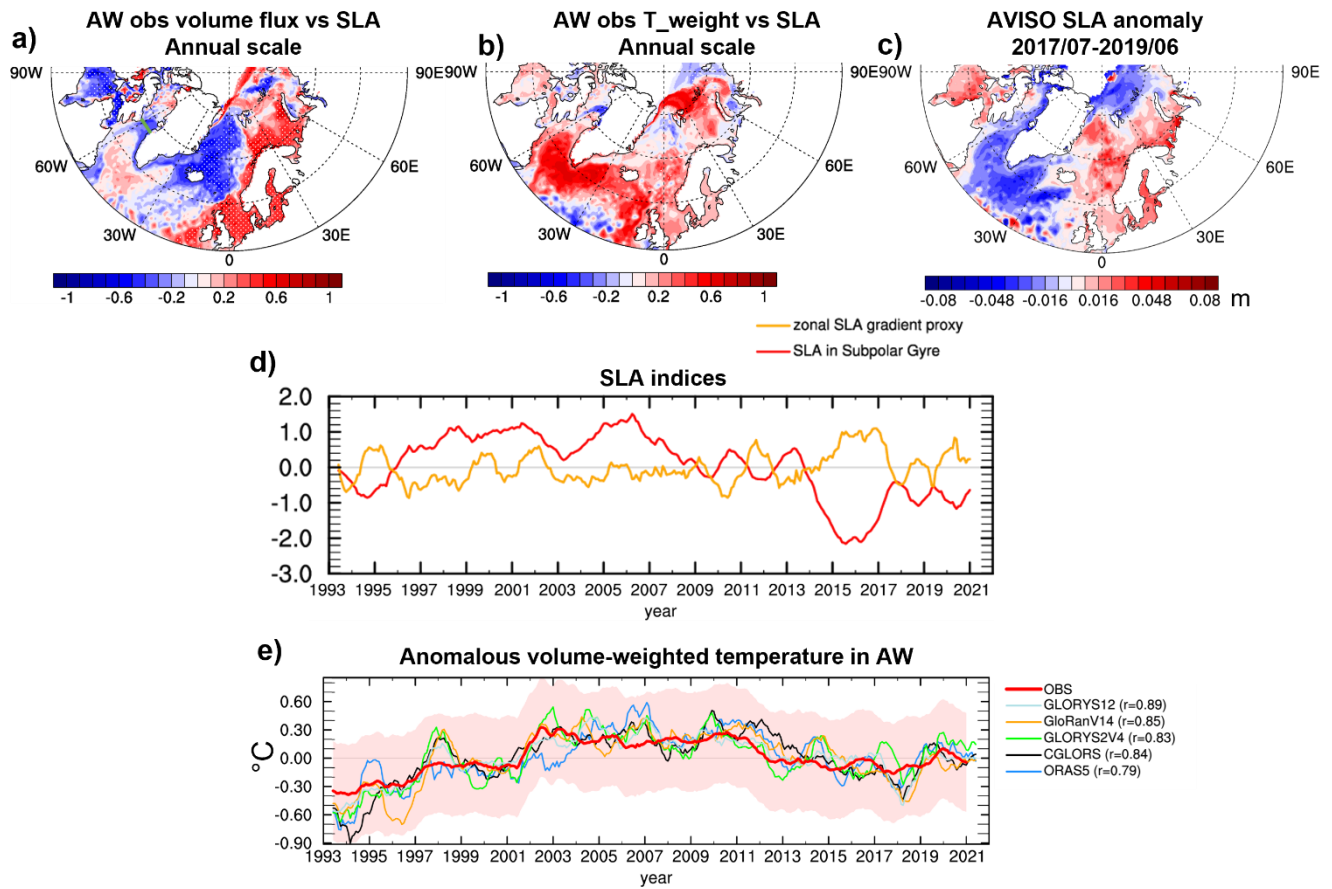

Fig. 2. Mean annual cycle of (a) AW volume flux (b), OW volume flux, (c) PW volume flux, and (d) GSR total (AW+PW+OW) heat flux; Temporal anomalies of (e) AW volume flux and (f) GSR total heat flux. The red shading indicates ± 1 standard error of the observational data. Temporal correlations of reanalyses with observations are provided in the legends.

435 **Fig. 3.** Longitude-depth sections of a) mean temperature (with water mass boundaries indicated), b) mean velocity, c) 2017/07-2019/06 anomalous temperature, and e) 2017/07-2019/06 anomalous velocity across GSR based on GLORYS12 (stippling denotes grid cells where anomalies are $>2\sigma$ of biennial anomalies). Note that the section does not everywhere go along the shallowest part of Denmark Strait and I-F channel, leading to deeper trenches in some places (see also Fig. 1); time series of e) anomalous volume and f) anomalous temperature flux through Faroe-Shetland Branch, where the red shading indicates ± 1 standard error of the observational data. Temporal correlations of reanalyses with observations are provided in the legends.

440

445 **Fig. 4.** Correlation of observation-based a) AW volume flux and b) AW flux-weighted temperature with SLA with a 12-monthly smoother applied; c) SLA anomaly in 2017/07-2019/06; d) temporal evolution (standardized) of two SLA-based indices based on the zonal SLA gradient at GSR and the SLA in the SPG region; e) temporal evolution of volume-weighted temperature (T_{weight}) anomalies of Atlantic waters at the GSR (red shading indicates ± 1 standard error of the observational data and temporal correlations of reanalyses with observations are provided in the legend). Stippling in a) and b) denotes statistically significant correlations on the 95% confidence level.
