Abstract. In 2022, large parts of the Baltic Sea surface experienced the third-warmest to the warmest temperatures over the summer and autumn ~~temperatures~~months since 1997. Warm temperature anomalies ~~are a precondition for~~can lead to marine heatwaves (MHWs), which are discrete periods of anomalous high temperatures relative to the usual local conditions. Here, we describe the overall sea surface temperature (SST) conditions observed in the Baltic Sea in 2022 and provide a spatio-temporal description of surface MHW events based on remote sensing, model reanalyses and in-situ station data. ~~Most~~The most MHWs, ~~four and~~ locally ~~even~~ up to seven MHW events, were detected in the western Baltic Sea and the Inner Danish Straits, where maximum MHW intensities reached values of up to 4.6 °C above the climatological mean. The ~~Northern~~ northern Baltic Proper and the Gulf of Bothnia were impacted ~~by~~ mainly by two MHWs at maximum intensities of 7.3 °C and 9.6 °C, respectively. Our results also reveal that MHWs in the upper layer occur at a different period than at the bottom layers and are likely driven by different mechanisms. ~~Results~~Model data from ~~the case studies at~~ two exemplary stations, 'Lighthouse Kiel (LT Kiel)' and 'Northern Baltic', show a significant increase ~~of~~in MHW occurrences, of +0.~~7~~73 MHW events per decade at LT Kiel ~~from 1989 to 2022~~ and of +0.64 MHW events per decade ~~from 1993 to 2022~~ at Northern Baltic~~.~~, between 1993 and 2022. Moreover, we discuss the expected future ~~increase of MHW occurrences is discussed~~increased occurrence of MHWs based on a statistical analysis at both locations.

1 Introduction

Global warming has ~~manifested itself through the~~led to an increase of ocean heat content (OHC) by about 350 ZJ in the upper 2000 meters from 1958 to 2019, with the year 2022 being the warmest on record as of this writing (Cheng et al., 2022; WMO, 2023). Simultaneously, marine heatwaves (MHWs), ~~the~~ extreme events of high water temperature (Hobday et al., 2016), have increased in ~~their~~ frequency, duration, spatial extent and intensity during the past four decades (Sun et al., 2023). In 2022, MHWs were recorded on 58 % of the ocean surface (WMO, 2023).

The ~~global mean air temperature in 2022 was 1.15 [1.02–1.28] °C above the 1850–1900 average, resulting in the year 2022 to be the fifth or sixth warmest year in the 173-year instrumental record (WMO, 2023). We could hence expect the marginal seas like the Baltic Sea to experience high sea surface temperatures (SST) as well. This hypothesis is supported by the study which showed that the extremely warm weather conditions in winter 2019/20 resulted in an unusually high heat content anomaly in the upper 50 m layer of the Baltic Sea (Raudsepp et al., 2022). Thus, a large-scale weather pattern could have a detectable response to the physical conditions of the Baltic Sea.~~

~~Belkin (2009) showed that the~~ Baltic Sea is one of the ~~seas which have warmed~~ marine ecosystems with the fastest ~~in the last decades with a~~recorded warming of surface temperatures of 1.35 ~~K~~°C between 1982 and 2006, i.e., 0.54 °C per decade~~. In our BSH~~ (Belkin, 2009). SST data ~~(~~operationally produced by the German Federal Maritime and Hydrographic Agency (in the following BSH, product ref. no. 1 in Table 1) ~~we see~~show a warming trend of 0.58 °C per decade for the period 1990–2022 ~~(based on annual means derived from satellite data, not shown). Local air sea heat exchange is the main physical factor that determines the surface layer water temperature and heat content in the Baltic Sea (Raudsepp et al., 2022). A permanent halocline at the depth of 60–80 m (Väli et al., 2013) limits heat exchange between surface and lower layers. Further on, limited water exchange of the Baltic Sea with the open ocean through the Skagerrak potentially reduces heat transport between the sea and the ocean.~~

~~MHWs are usually detected using remotely sensed SST.~~. High ~~SST could~~SSTs can affect phytoplankton production, while unprecedented high temperatures in the subsurface layers of the sea could have even more devastating effects on the marine ecosystem (Kauppi et al., ~~2023). Subsurface layer MHWs can be detected using temperature moorings, though unfortunately these moorings provide only point measurements. Numerical models enhance the possibility for studying dynamics of MHWs including their extension to the subsurface layers of the ocean. In this study we utilize remote sensing, model reanalyses and in-situ station data for the spatio-temporal description of the MHWs in the Baltic Sea in 2022. So far, there are generally only a few studies about MHWs in the Baltic Sea (Goebeler at al.,~~ 2023). Conditions that facilitate the fast warming of the Baltic Sea are the limited exchange between surface and deeper layers due to a permanent halocline at a depth of 60–80 m (Väli et al., 2013) and the limited water exchange between the Baltic Sea and the open ocean through the narrow Skagerrak. That is why local air-sea heat exchange is the main physical factor for the surface layer water temperature and heat content in the Baltic Sea (Raudsepp et al., 2022). ~~2022; She et al., 2020). In addition to the detailed description of MHWs in 2022 we extended our study by providing climatology of the MHWs based on mooring station data.~~

~~Maps~~Global mean air temperature in 2022 was among the six warmest in the 173-year instrumental record (WMO, 2023). For Europe especially, the Copernicus Climate Change Service/ECMWF (2022a) states that the air temperatures in August 2022 were higher than the 1991–2020 average across most of the continent, especially in a band in Eastern Europe stretching from the Barents and Kara seas to the Caucasus. In November 2022, air temperatures were higher than the 1991–2020 average, especially over the west, south-east and far north of Europe, and were unusually mild over the northern European seas (Copernicus Climate Change Service/ECMWF, 2022b). These large-scale weather patterns likely lead to high sea surface temperatures (SST) in marginal seas like the Baltic Sea and are a likely driver of MHWs. This hypothesis is further supported by a study by Holbrook et al. (2019), which found that MHWs at middle and high latitude regions were driven by large-scale atmospheric pressure anomalies which cause anomalous ocean warming. Stalled atmospheric high-pressure systems coincide with clear skies, warm air, and reduced wind speeds. These conditions then lead to quick warming of the upper ocean and increased thermal stratification due to reduced vertical mixing.

So far, there generally have been only a few studies on MHWs in the Baltic Sea (Goebeler at al., 2022; She et al., 2020). ~~satellite~~In this study, we show that remote sensing data revealed several SST anomalies over the entire Baltic Sea in 2022. We thus use model reanalysis and in-situ station data to provide a spatio-temporal description of the corresponding MHWs. Both datasets contain data collected over a long enough period to also provide its own respective climatology, thereby enabling a consistent representation of MHWs. While the in-situ data provides accurate point-wise measurements of the temperature at selected locations, the model reanalysis data allows for a widespread analysis of MHWs over the entire Baltic Sea, including their extension into subsurface layers. Furthermore, we extend our study by providing a climatology of MHWs at two specific mooring locations, namely at the Lighthouse Kiel (LT Kiel) and Northern Baltic stations. The overall aim of this study is to highlight the areas of the Baltic Sea that were (most) affected by MHWs and determine whether surface MHWs can propagate into deeper layers and thus potentially threaten the subsurface ecosystem. Furthermore, analyzing the climatology of MHWs can provide insight into whether the global increase in MHWs can also be expected to occur on a local scale for the Baltic Sea.

2 Data and Methods

2.1 Satellite data

The satellite data service at the BSH compiles daily maps of SST data (product ref. no. 1 in Table 1). ~~, as,~~These have contributed for example~~, used~~ to studies by ~~T~~the BACC Author Team (2008) and Gröger et al. ~~(2022), are compiled daily by the satellite data service at BSH (product ref.~~ (2022). The SST ~~no. 1 in Table 1). These~~ data are recorded as radiances by the ~~third generation of the~~ Advanced Very High Resolution Radiometer (AVHRR/3) in ~~channels 4 and 5 centered at wavelengths 10.8 µm and 12.0 µm in the~~ two thermal infrared ~~respectively (EUMETSAT, 2015). The AVHRR/3 instruments used are flown~~ channels aboard the ~~polar orbiting~~ NOAA-19 and MetOp B satellites, providing a spatial resolution of 1.1 km ~~directly below the instrument (in nadir),~~, swath widths of 1,447 km and orbital periods of 100 minutes (EUMETSAT, 2015; Minnett et al., 2019). ~~This results in generally 8~~The raw data of eight or ~~9~~nine daytime passes over the Baltic and North Sea ~~area per day. The raw data (level 0)~~ are received directly from EUMETSAT ~~90 minutes after flyover~~ and processed using automated, standardized correction procedures (atmospheric correction, cloud masking, georeferencing etc.). Additionally, each flyover is corrected manually in order to preserve as much data as possible whilst eliminating any faulty or cloudy pixels. All available single images from a calendar day are combined and averaged, on a single pixel basis, into one daily-mean image. These daily images are then used to produce a weekly analysis on an operational basis. This weekly analysis is produced on an equidistant grid of 58 by 74 cells in 20 km resolution, making use of an oblique Lambert projection with an origin at 56° N, 4° W (center of the BSH North Sea SST analysis). All daily satellite pixels falling into a 20x20 km grid box are considered equally when calculating a weekly average for this particular 20x20 km grid box. Eventually, the result for the weekly average is smoothed using a binomial filter (50 % weight for the grid box itself, 50 % for its respective neighbors). While the BSH has been carrying out the processing of the satellite data itself on the 1.1 km grid has been carried out at BSH since 1990, the operational SST analysis for the Baltic Sea did not start until the autumn of 1996. The analysis of the BSH SST dataset presented in this chapter is therefore constrainedlimited to the period from 1997–2022.

2.2 Station data

In-situ temperature time series from mooring stations which are located in the Baltic Sea are obtained from product ref. used for 1) model validation and 2) cross validation of the MHW computation from model data. Exceptno. 2 in Table 1, except for SST data from Northern Baltic (K. Hedi, FMI, pers. communication), the station data are obtained from product ref. no.).2 in Table 1. Each available dataset has already been quality controlled by the regional production units (In Situ TAC partners, 2022). The temporal resolution varies from hourly data at the German stations andto half-hourly at the stations in the northern Baltic Proper and Gulf of Finland. Due to failures, maintenance and other circumstances, no mooring station entirely covers the period from 1st Jan 1993 until now entirely.

FromOf all available mooring stations, those arewe selected those which contain data from 2022 and from at least ten additional years from 1993 until 2021 in at least one depth. Out of the then remaining seven mooring stations that contained surface temperature data, two mooring stations were chosen for the additional modelcross validation and the analysis of MHWs: Lighthouse Kiel (LT Kiel) and Northern Baltic. (Fig. 1). Of the observation data, LT Kiel has the largestgreatest time coverage of observation data (rather continuously from (1989 until the present). It , missing data: 9.1 % of days). This mooring station lies in the far western part of the southern Baltic, and the water depth at this mooring station there is about 12 m. On the other hand,The station Northern Baltic is located in the northern Baltic Proper and provides measurements down to water depths of 103.8 m.. The SST observations there cover the period from 1997 until now, rendering it an ideal candidate for evaluating the effects of MHWs into (missing data: 8.0 % of days). No mooring station provides a time series in deeper layers long or consistent enough to analyze subsurface MHWs, thus reducing the scope of measurement-based analysis of MHWs to the surface layers.

2.3 Baltic Sea Physics Reanalysis Data

The Baltic Sea physics reanalysis product (product ref. no. 3 in Table 1) is a model dataset produced by usingbased on the ocean model NEMO v4.0, a state-of-the art oceanographic modeling framework (Gurvan et al., 2019). The model system assimilates satellite observations of SST (EU Copernicus Marine Service Product, 2022b) and in-situ temperature and salinity profile observations from the ICES database (ICES Bottle and low-resolution CTD dataset, 2022). The product provides gridded information on SST and subsurface temperature conditions. The spatial coverage is 1 ~~nm and~~nautical mile, i.e., approximately 1.8 km. The grid covers the entire Baltic Sea, including the transition zone to the North Sea, with a vertical resolution of 56 non-equidistant depth levels. This multi-year product (MYP) covers the reference period from 1993 up to 2022. The model setup is described in the Product User Manual (PUM, Ringgaard et al., 2023).

2.4 ~~Model validation~~

~~Although the Baltic Sea physics reanalysis product (product ref. no. 3 in Table 1) has already been extensively validated in the corresponding Quality Information Document (QuID; Panteleit et al., 2023), the model data is additionally validated for this chapter at different mooring stations, in particular LT Kiel and Northern Baltic, using the available station data (product ref. no. 2 in Table 1) and the full reference period from 1993 to 2022. Hence, in this case, only mooring stations were validated which are mostly located in the southern Baltic, whereas the validation in the QuID also considered ICES data which covered the entire Baltic Sea. Our evaluation confirms the results from the QuiD, for example, that the MYP underestimates the temperature at the surface which, on average, results in a negative bias. Nevertheless, as can be clearly seen in Fig. 1, the temperature curves at Northern Baltic and LT Kiel, respectively, show the same progression. The generally lower temperature in the MYP results in a slightly lower temperature climatology and threshold (here, the 90th percentile), respectively, on which the MHW detection is based. In general though, the MHWs and their respective intensities and lengths are detected equally in both the station and model data.~~

~~While the bias at the surface is between -0.46 °C and -0.2 °C, the bias at deeper levels shifts towards more positive values. At the deepest levels where observational data is available, the bias in our validation ranges from -0.22 °C to 0.43 °C which also corresponds to the results in the QuID (-0.36 °C to 0.26 °C). This means that the model bias varies at depth and with that maybe also the accuracy. To ensure the quality of the used station data from Northern Baltic, the validation of the lower level at the station BMPH2 from the QuID can be used as an approximation. BMPH2 is located only 43 km from Northern Baltic and reaches a depth of 150 m (in contrast to Northern Baltic with 105 m). It is a monitoring station which is operated by vessels and CTD casts are used to obtain measurements. These casts provide measurements at multiple depths, but are unevenly distributed over time (Panteleit et al., 2023). Unfortunately, there is no observation data available after 2019. With a bias of -0.15 °C and a centered pattern root mean square difference (cRMSD) of 0.17 °C the model data fits quite well to the station data (Fig. 1).~~

~~2.5~~ Heat wave detection

Marine heatwaves ~~(MHWs)~~ refer to a discrete period of unusually high seawater temperatures. While ~~there are~~ several definitions ~~to~~describe MHWs quantitatively ~~describe MHWs~~, the most commonly used method defines them as periods when temperatures exceed the 90th percentile of the local climatology for five days or more (Hobday et al. 2016). ~~Here, we apply the python package for MHW detection and statistics by~~ We use open-source tools to detect MHWs (Oliver ~~(~~, 2016~~) to the observational data and the Matlab package by~~; Zhao and Marin ~~(~~, 2019) ~~for the MHW statistics based on the~~ in station and model data. ~~These packages have been shown to produce identical results (Zhao and Marin, 2019).~~ The ~~classification of~~identified MHWs ~~follows~~can be classified following Hobday et al. (2018), ~~where~~in which the ~~resulting~~MHW category is based on the maximum intensity in multiples of threshold exceedances, i.e., the local difference between the 90th percentile threshold and the climatology. If the threshold is exceeded ~~by~~ less than 2 times ~~this local difference~~, the MHW is classified as moderate (Category I), at 2 to 3 times it is classified as strong (Category II), at 3 to 4 times it is classified as severe (Category III), and at 4 ~~times~~ or more times it is classified as extreme (Category IV).

~~For~~Here, the ~~assessment~~occurrence of MHWs in the Baltic ~~domain during~~ Sea in 2022 ~~(Sect. 3.2), the climatological data of 1993 to 2022 as well as the data of 2022 are collected from~~is analyzed based on the Baltic Sea MYP (product ref. no 3 in Table 1). The following statistical metrics of MHWs are computed at ~~each available~~every third surface grid point of the ~~reanalysis~~MYP, resulting in a resolution of approximately 5.4 km: cumulative intensity, mean intensity, duration of the longest heatwave, number of heatwaves (frequency), maximum intensity and total days of MHW conditions.

~~In~~Then, in order to evaluate the development of those MHW metrics over time, block averages (using a block length of one year) for each MHW metric are computed for ~~the time series data at the two mooring stations, for~~ both the observations (product ref. no 2 in Table 1) and the model data~~. We then also compute the linear trend (95~~ (product ref. no 3 in Table 1) at two stations: Lighthouse Kiel and Northern Baltic. The yearly MHW metrics from observations and the model are correlated for evaluation, and linear trends (95 % significance) are calculated for each of those ~~annual MHW~~ metrics. Finally, the correlation of the annual MHW metrics to the annual mean temperature based on model data was assessed using a linear least-squares regression and a two-sided t-test for significance.

All MHW assessments in the following sections use the period from 1993 to 2021 for the climatology, except for Sect. 3.2.1, in which the comparison of the multi-year evolution of MHWs at Northern Baltic uses the overlapping period from 1997 to 2021 due to the lack of observations at this station before 1997.

2.5 Model validation

The MYP data has already been extensively validated in the corresponding Quality Information Document (QuID; Panteleit et al., 2023). In this document, the MYP data are validated within the time period from 1st January 1993 to 31st December 2018. The validation shows a negative bias at the surface with a shift towards more positive values at deeper levels. A variation of statistical values with depth is also clearly visible in the estimated accuracy number (EAN), which represents the root-mean square difference (RMSD) of a specific depth layer. The RMSD varies between 0.29 °C at 200–400 m over 0.63 °C at the surface to 1.3 °C at 5–30 m depth.

We additionally evaluated the model data in more detail using a clustering approach, which offers insights into the overall accuracy of the model by grouping the errors. This clustering procedure employs the K-means algorithm (Raudsepp and Maljutenko, 2022). In this evaluation, all available data within the model's domain and simulation period are considered. A two-dimensional error space (dS, dT) is established using simultaneously measured temperature and salinity values as the foundation for clustering. Here, $dS=(S_{mod}-S_{obs})$ and $dT=(T_{mod}-T_{obs})$ represent the differences between the model (S_{mod} and T_{mod}) and observed (S_{obs} and T_{obs}) salinity and temperature, respectively. The dataset employed in this validation study was sourced from the EMODNET dataset compiled by SMHI (product ref. no. 4 in Table 1). It consists of a total of 3,094,089 observations aligning with the simulation period of the Baltic Sea physics reanalysis (product ref. no. 3 in Table 1) and covering the years 1993 to 2022. A comprehensive explanation of the k-means-method and detailed results describing the model's accuracy can be found in Appendix A1. The results can be summarized as in that approximately 82 % of all validation points exhibit relatively low temperature bias, STD, and RMSD (Table A1). The surface layer validation shows that less than 10 % of comparison points have significant temperature errors (Figure A1c). Due to the low proportion of these validation points we do not expect a significant impact on the determination of the surface MHWs and their statistics. Below the surface layer, i.e., at depths ranging from 0.5–40 m, up to 25 % of the points correspond to clusters with temperature errors greater than +/- 2.0 °C; in deeper layers, this percentage gets smaller again (Figure A1c). Consequently, we anticipate that the model reanalysis data provide sufficiently accurate information for calculating subsurface MHWs and their statistics for the Baltic Sea as well.

The model is also validated in terms of how accurately it reproduces the MHWs of 2022 and how well it represents their characteristics during the overlapping time periods of data availability at the two locations (1993–2022 for LT Kiel, and 1997–2022 for Northern Baltic). For this, the model data was compared to the available station data (product ref. no 2 in Table 1 for LT Kiel and K. Hedi, FMI, pers. communication for Northern Baltic) at these locations. Table 2 shows the Pearson correlation coefficients for the MHW metrics in Fig 4 between observational and model data for the two stations, which show overall good agreement between the model and the observation data with respect to MHW detection.

We also compared the annual temperature curves resulting from both the model and the station data at each location (Fig. A2). Overall, the curves show the same progression. The temperature from the MYP is generally slightly lower, and consequently this results in a slightly lower temperature climatology and threshold (here, the 90th percentile) on which MHW detection is based. In general, though, the MHWs and their respective intensities and lengths are detected equally in both the station and model data.

3 Results

3.1 Sea surface temperature anomalies in satellite data

~~During~~In the summer ~~months~~of 2022, large parts of the Baltic Sea featured strong warm anomalies based on the BSH SST analysis (product ref. no. ~~with~~ 1 in Table 1, Fig. 2). The highest values ~~of~~were up to 3 °C above the long-term mean (1997–2021) in the Bothnian Sea in June and in the Bothnian Bay in July~~, respectively (Fig. 2).~~. In August however, these areas ~~exhibit rather~~were neutral ~~to~~or exhibited cold anomalies, while the Baltic Proper as well as the Gulf of Finland and the Gulf of Riga showed the warmest anomalies of +1.5 °C to 2.5 °C. ~~In~~At the beginning of autumn, the Baltic Sea is marked by a substantial east-to-west gradient ~~regarding~~of SST anomalies~~. This is~~ due to a series of upwelling events along ~~the~~its eastern ~~coastlines of the Baltic Sea.~~shores. In November, ~~again~~ the whole Baltic Sea features strong warm anomalies, again with peak values above +2 °C around Southern Sweden.

To provide some climatological context ~~of~~for the observed SST anomalies in a straightforward way, we also present maps ~~of~~ranking the SST ~~anomaly ranks~~anomalies for the summer and autumn months ~~in~~of 2022 ~~when compared to their respective~~against the same months in previous years (right two columns of Fig. ~~2). It is obvious that the warm anomalies found~~ 2). These anomaly rankings provide information on how extreme an anomaly of a given magnitude is. For every grid point and for each calendar month, the monthly anomalies are ranked by magnitude. The warm anomalies over large parts of the Baltic Sea during the summer and autumn of 2022 ~~belong to~~are among the warmest eight on record for the respective months. ~~Except for~~In September~~ when the~~, coastal upwelling ~~along the eastern coastlines~~ led to cold anomalies ~~contrasting the warm anomalies in the western half of the Baltic Sea, it is found for basically all~~ along the eastern shores, but the other five months of the summer and fall of 2022 (June~~ through~~, July and August~~,~~ as well as October and November) ~~that~~show large areas of the Baltic Sea ~~featured~~with warm anomalies ~~belonging to~~that are among the~~ highest~~ four most pronounced on record. ~~For~~In August and November, we ~~even find~~see several large~~r~~ areas along the coastlines of the Baltic countries as well as off the Polish coast and around Gotland that ~~featured surface temperatures being the highest ever~~ according to the BSH SST analysis ~~(product ref.~~ dataset featured highest-ever surface temperatures. ~~no. 1 in Table 1).~~

3.2 Marine heatwaves

~~Temperature~~ MHWs describe exceptionally warm temperature anomalies~~ are a precondition for MHWs. The~~. As the monthly overview in Fig. 2 already provides an indication of possible MHW conditions~~. To begin with, these are assessed by using the statistical~~ in 2022, the MHW metrics defined by Hobday et al. (2016) ~~at each grid point based on the SST data extracted from~~are assessed using the Baltic Sea MYP (product ref. no. 3 in Table 1). Each region of the Baltic Sea experienced different MHW characteristics during 2022 (Fig. 3~~).~~, Table 3).

The most MHWs during 2022 ~~were detected~~occurred in the Inner Danish Straits and the Western Baltic (Fig. 3d~~). Mainly 4~~); mainly, four to ~~5~~five MHWs were detected~~. At~~, with some assessed ~~grid points,~~locations experiencing up to ~~7~~seven MHWs

~~are detected, which leads to~~ and a maximum of ~~96~~94 total days of MHW conditions ~~in that area~~ (Fig. 3f). The mean and maximum intensit~~y~~ies of all ~~heatwaves~~MHWs in ~~these areas~~the Western Baltic reached up to 3.8 °C and 4.6 °C, respectively (Fig. 3b and 3e). The highest ~~values in~~ mean and maximum intensity ~~of MHWs~~values were reached in the ~~N~~northern Baltic Proper ~~(up to 5.3 °C, resp. 7.3 °C) as well as the Gulf of Bothnia (up to 6.5 °C, resp. 9.6 °C).~~and in the Bothnian Sea and Bothnian Bay (Fig. 3b and 3e), though these regions were affected mainly by only two MHWs. The maximum ~~intensities were even~~intensity in the Bothnian Bay even reached 9.6 °C, the highest within the entire studied period from 1993 to 2022. ~~Those regions were impacted by mainly two MHWs, but at some individual grid points up to six MHWs are identified with a maximum value of up to 63 days with MHW qualification. While the duration of the~~The longest MHW is ~~similar in both regions (Fig.~~ found in the Baltic Proper (32 days), followed by the Bothnian Sea (31 days) and the Inner Danish Straits (29 days) (Fig. 3c)~~,~~. ~~t~~The highest values of cumulative intensity (of a single MHW~~) are found in the Gulf of Bothnia in the Kvarken (~~), with up to 119.3 days °C~~), while the values in the Western Baltic and Inner Danish Straits are lower (up to 64 days °C) (Fig.~~ , are found in the Kvarken, a strait between the Bothnian Sea and~~3a).~~
~~Compared with Fig. 2,~~ the Bothnian Bay (Fig. 3a).~~MHW with the highest cumulative intensity in the Gulf of Bothnia derives from the temperature anomaly in November. The numerous MHWs in the Western Baltic and the large number of days with MHW conditions connected with them occurred in both the summer and autumn months.~~

3.2.1 Multi-year evaluation of MHW metrics

Next, we assess the frequency and other characteristics of the MHWs that occurred in 2022 in a climatological context based on both observations and model data for the two stations, LT Kiel (~~for~~based on the overlapping climatology period 1993–202~~2~~1, Fig. 4a–h) and Northern Baltic (~~for~~based on the overlapping climatology period 1997–202~~2~~1, Fig. 4 i–p). Overall, the results for the yearly MHW metric calculation are well correlated between the observations and the model data (Table 2).
In 2022, ~~in~~a total of five MHWs (four in the MYP) occurred throughout the year at LT Kiel~~, spread out through the year~~ (Fig. ~~1a~~A2a). Though none of ~~the 2022 MHWs~~them was extraordinarily long or intense at LT Kiel, the ~~station data~~time series of yearly MHW metrics shows that, based on observational data, the number of MHW occurrences in 2022 was the second highest ~~after 2020~~there since 1989 (Fig. 4a). The time series of MHW frequenc~~y~~ies per year suggests that the occurrence of MHW events has increased over the last three decades (Fig. 4a). Th~~is~~e trend ~~of~~ computed from model data is +0.~~7~~73 MHWs per decade ~~becomes statistically significant when all~~for the ~~available station data from 1989~~period 1993–2022 ~~is taken into account~~. The number of MHW events per year is positively correlated (R=0.76) with the increasing annual mean SST at th~~at~~is mooring station (Fig. 4b). The maximum (Fig. 4c) and cumulative intensities (Fig. 4e) of observed MHWs do not show a clear trend and are not correlated to ~~rising~~the warming annual mean temperatures (Fig. 4d and Fig. 4f). There is no significant trend in total MHW days (Fig. 4g) at LT Kiel, but a positive correlation (R=0.71) with rising average temperatures (Fig. 4h).

For Northern Baltic, neither the station data nor the model data exhibits a statistically significant trend in MHW events for the overlapping period (Fig. 4i). But when all of the available model data from 1993–2022 is taken into account, the trend in MHW occurrences becomes significant at the 95 % level, with +0.64 MHWs per decade. Again, the number of events is positively correlated with annual mean temperature (R=0.58, Fig. 4j). The highest maximum MHW intensities were recorded in recent years (2016, 2018, 2021, 2022~~)~~), with 2022 showing the highest intensity of ~~a~~any MHW~~ with~~, at 7.3 °C (model data) to 7.4 °C (station data) above the climatologically expected temperature (Fig. 4k,l, see also Fig. ~~1b~~A2b). The cumulative MHW intensities show no clear trend or correlation with annual mean temperatures at this station (Fig. 4m,n). In terms of total MHW days, 2018 ~~was exceptional~~shows the highest numbers (Fig. 4o), but otherwise no trend is detectable for this metric, though there is positive correlation with annual mean temperatures (R=0.56, Fig. 4p).

3.2.2 Analysis of vertical MHW distribution at Northern Baltic

At Northern Baltic, which is ~~more than 104~~about 103 m deep and located in the Western Baltic Proper, the surface temperature has been measured continuously ~~measured~~ over several decades. Unfortunately, no quality-controlled temperature measurements exist ~~in~~for the lower layers~~. In Sect. 2.4 we showed that the~~ at this station. The model ~~data coincides~~validation shows that, at other locations, the model represents temperatures generally well~~ with observational data~~, both at the surface and in the lower layers. ~~Thus, in~~In order to obtain further insights into~~ the~~ heat wave propagation towards the seafloor, we analyzed the MYP model data (product ref. no. 3 in Table 1) along the entire water column.

A seasonal SST signal is clearly visible in Fig. 5a. In general, the temperature tends to decrease with depth while the bottom temperature is relatively cold and uniform. In ~~late spring~~early summer (June), a so-called cold intermediate layer (CIL~~) at a depth of 20-60 m, which is~~), defined as a minimum of temperature between the thermocline and the perennial halocline (Chubarenko et al., 2017; Dutheil et al., ~~2022), is formed. The upper boundary of the CIL is in good agreement with the mixed layer depth. The CIL~~2022), develops at a depth of 20–60 m and acts as a barrier between the surface and bottom water ~~body and has~~ bodies. At Northern Baltic, the upper boundary of the CIL coincides with the mixed layer depth (MLD), which is depicted in Fig. 5b-c. Starting from around June, a layer of water with a significantly lower temperature ~~(Fig. 5b) of -0.3 °C to 4.5 °C as the climatological mean. As shown in Fig. 5c and Fig. 5d, the intensity of the MHW tends to decrease as the depth increases. MHWs in regions close to the seafloor were detected during specific periods from February to April, September to October and in December. During July, a one day extreme MHW (Category IV) event was observed at the surface with 7.4 °C above the climatological mean temperature, followed by further three days with a severe MHW (Category III). A few weeks prior to this MHW (and in 10.8 m depth also afterwards), the temperature was already significantly higher~~ than the climatological mean~~, but~~ (up to -7 °C deviation) is found just below the MLD (Fig. 5b), which suggests that the CIL was significantly colder at this time in 2022. This also coincides with the onset of significantly higher temperatures at the surface compared to the climatological mean, though these were initially not high enough to result in a MHW (Fig. 5e~~ and 5f~~). The elevated temperatures start~~ed~~ with a significant temperature jump of 5~~-~~ °C above the climatological mean, followed by ~~an~~ abrupt and substantial ~~in~~decreases and ~~de~~increases in temperature over a short period ~~(Fig. 5e).~~. This eventually leads to a MHW which lasts for 15 days starting from the end of June and which contains a one-day extreme MHW (Category IV) event at a temperature of 7.4 °C above the climatological mean, followed by a severe MHW (Category III) for another three days. Significantly high temperature deviations can also be observed at a depth of 10.8 m, i.e., at the MLD, after July 2nd, just after the Category IV MHW at the surface. However, these temperature deviations did not result in a MHW at this depth. Following th~~is~~e extreme heatwave event at the surface, a comparably weaker MHW ~~is observed~~ can be detected in mid-August~~. The weaker August MHW is observable~~ at both 0.5~~-~~ m (Fig.~~-~~ 5e) and 10.8~~-~~ m (Fig.~~-~~ 5f~~), while the June~~). Thus, this weaker MHW ~~is already no longer noticeable below the mixed layer depth.~~ penetrates past the MLD into slightly deeper levels before reaching the comparably cold layer of water underneath.

As shown in Fig. 5c and Fig. 5d, the intensity of the MHW tends to decrease as the depth increases. Four MHWs in regions close to the seafloor (i.e., below 60 m) were detected during specific periods from February to April, September to October, and in December. These MHWs are mostly moderate, with temperatures reaching up to 1.59 °C above the climatological mean. Only three days at the end of September can be classified as a Category II MHW in one specific depth-layer close to the seafloor. In the bottom-most depth-layer, the corresponding subsurface MHW is interrupted by five days of temperatures below the 90th percentile. However, as the temperatures are only slightly below the threshold and the MHW criteria are still met in the depth-layers above, one might still count this as one continuous MHW. Furthermore, Fig. 5c also shows isolated Category I MHWs at depths between 20 and 50 m.

4 Discussion and Conclusions

During August and November 2022, record~~-~~-warm sea surface temperatures were observed in substantial areas ~~in~~of the Baltic Sea proper. Large parts of the Baltic Sea exhibited the third-warmest to the warmest temperatures in summer ~~or~~and autumn ~~temperatures~~months since 1997. Both periods, in August and November, coincided with atmospheric temperature anomalies. ~~In August air temperatures were higher than~~ Over the ~~1991–2020 average across most of Europe, especially in Eastern Europe, in a band stretching from the Barents and Kara seas to the Caucasus (Copernicus Climate Change Service/ECMWF, 2022a). In November~~ entire year of 2022, ~~air temperatures were higher than the 1991–2020 average especially over the west, south-east and far north of Europe and unusually mild over the northern European seas (Copernicus Climate Change Service/ECMWF, 2022b). These atmospheric surface temperature anomalies are a likely driver for MHWs since they seem to coincide with the observed marine surface temperature anomalies. Holbrook et al. (2019) found that the MHWs they studied at middle and high latitude regions were driven by large-scale atmospheric pressure anomalies which cause anomalous ocean warming. Stalled ridges of atmospheric high-pressure systems coincide with clear skies, warm air, and reduced wind speeds. These conditions lead to quick warming of the upper ocean and increase thermal stratification due to reduced vertical mixing.~~

~~In 2022, MHWs occurred in all marginal seas of Europe where the Baltic Sea was not an exception. The~~the distribution of quantity and intensity of MHWs within the Baltic Sea is twofold: ~~Up~~up to seven individual MHW occurrences were ~~both~~ recorded ~~and~~as well as simulated in the south-western part of the Baltic Sea, ~~which lead to the fact that~~and as a result this region experienced the maximum number of total MHW days ~~in the~~ of anywhere in the Baltic Sea in 2022. In the northern Baltic Sea ~~in 2022. In,~~ the ~~northern part, the total~~ number of MHWs was lower, with ~~locally~~some locations registering only one MHW ~~being detected. Remarkably~~; remarkably, however, this one MHW ~~also~~ led to the highest mean and maximum MHW intensities in the Baltic Sea since the reanalysis started in 1993~~:~~. In some areas~~,~~ in the Bothnian Bay, the Baltic Sea MYP revealed temperatures that exceeded 9 °C above the 90th percentile of the climatologically expected temperature values~~.~~ (Fig. 3d,e). This can be considered an extraordinarily high MHW intensity, since maximum SST anomalies above 5 °C have only been observed in about 5 % of the global ocean, and MHW intensities normally peak at 2.5 °C to 3.7 °C (Sen Gupta et al., 2020). In our case, the area in the Bothnian Bay experienced a short period with southerly winds and air temperatures up to 28 °C at the end of June 2022 (SMHI, 2023), which led to a short, but very intense MHW in the shallow areas of the Bay.

~~At our two exemplary stations a~~A significant increase ~~of~~in MHW occurrences is detectable over time~~:~~ at our two exemplary stations, of +0.~~7~~73 MHW events per decade at LT Kiel and +0.64 MHW events per decade at Northern Baltic. ~~There is a statistical relationship between both~~Both MHW frequency and the total number of MHW days ~~with~~ are statistically related to rising mean temperatures. This confirms that~~, also in the Baltic Sea,~~ an increasing number of MHWs can be expected in the future in the Baltic Sea, too, due to global warming (Frölicher et al., 2018; Oliver et al., 2019). ~~Adverse~~The adverse impact of MHWs ~~to different~~ on the ecosystem's various trophic levels ~~of the ecosystem is~~ has been widely documented (Smale et al., 2019; IPCC, 2022; Smith et al., 2023). The Baltic Sea, which has a relatively vulnerable ecosystem, could experience a significant negative impact ~~due to~~from MHWs (Kauppi and Villnäs, 2022; Kauppi et al., ~~2023).~~ 2023), and the analysis of subsurface MHWs opens up further potential ways to study their effects. At the Northern Baltic mooring station, MHWs were found at the surface, propagating into deeper layers until reaching the CIL, and some were also detected close to the seafloor. Isolated MHWs were also observed at depths of between 20 and 50 m. However, these are subject to higher uncertainty compared to the ones in the surface and bottom layers due to a higher uncertainty in modeling variability in the pycnocline (QuID; Panteleit et al., 2023). Among the possible reasons for the development of the four MHWs close to the seafloor at Northern Baltic could be vertical heat transport from the surface or a lateral transport of warmer water due to bottom currents, for example. However, a more detailed evaluation would be required to assess their precise cause.

Potential avenues for future studies ~~opens up by~~include examining whether ~~the August MHW in 2022 could~~ and how surface MHWs are able to propagate into the deeper water masses close to the halocline ~~at Northern Baltic and also regarding~~as well as examining the correlation between the strength (i.e., the classification category) of the MHW and its propagation into deeper water masses~~ and the strength (i.e. classification) of the MHW. Further~~. At Northern Baltic, severe and extreme MHWs occurred at the surface when the CIL was particularly cold compared to the climatology. This therefore raises questions of whether a strong CIL might be linked to the development of MHWs at the surface and whether the one might even favor the development of the other. Additional studies could ~~determine if~~also focus on the positive feedback on the bottom temperature, ~~that~~as was observed in 2022~~,~~. It might be interesting to determine if this phenomenon can also be found in ~~following~~other years and whether ~~this phenomenon~~ it is triggered by the superposition of either lateral currents ~~and/~~or MHWs~~.~~ or of both together. Understanding the effects that potentially lead to the vertical propagation of MHWs~~,~~ like those observed particularly in the late summer~~,~~ of 2022 will become increasingly crucial in order to evaluate ~~the effects of~~how the already~~ rising occurrence~~ increasing occurrences of surface MHWs may affect the ecosystem in subsurface layers.

Appendix A1

We apply a clustering approach to evaluate the precision of the hydrodynamic model. This technique offers insights into the overall accuracy of the model by grouping the errors. The clustering procedure employs the K-means algorithm, a type of unsupervised machine learning (Jain, 2010). The original explanation of this technique can be found in a study by Raudsepp and Maljutenko (2022). In our evaluation, all available data within the model's domain and simulation period are considered, even if the observation data is unevenly distributed or occasionally sparse. This strategy enables us to assess the model's quality at each specific location and time instance at which measurements have been acquired.

Initially, a two-dimensional error space (dS, dT) was established using simultaneously-measured temperature and salinity values as the foundation for clustering. Here, dS=(S_{mod}-S_{obs}) and dT=(T_{mod}-T_{obs}) represent the differences between the model (S_{mod} and T_{mod}) and observed (S_{obs} and T_{obs}) salinity and temperature, respectively. The dataset employed in this validation study was sourced from the EMODNET dataset compiled by SMHI (product ref. no. 4 in Table 1). It consists of a total of 3,094,089 observations aligning with the simulation period of the Baltic Sea physics reanalysis (product ref. no. 3 in Table 1) and covering the years 1993 to 2022. For each observation, we extracted the nearest model values from the reanalysis dataset. The next stage involves choosing the number of clusters, and for simplicity we opted in advance for five clusters. Subsequently, the third step entails conducting K-means clustering on the two-dimensional errors. This clustering process is applied to the normalized errors achieved through separate normalization for temperature and salinity errors using the corresponding standard deviations. The K-means algorithm then identifies the centroids' positions within the error space for the predetermined number of clusters. These centroids' locations signify the bias of the error set for each cluster. In the fourth step, statistical metrics for non-normalized clustered errors are computed. Standard deviation (STD), root mean square deviation (RMSD) and the correlation coefficient are examples of common statistics that can be calculated for the parameters associated with each cluster. The fifth step involves examining the spatio-temporal distributions of errors associated with different clusters. During the creation of the error space, we retained the coordinates of each error point (dS, dT)(x, y), allowing us to map the errors of each cluster back onto the locations where the measurements were conducted. To achieve this, the model domain is partitioned into horizontal grid cells (i, j) of 27x27 km^2 in size. Subsequently, the number of error points attributed to various clusters at each grid cell (i, j) is tallied. The total number of error points linked to the grid cell (i, j) is the sum of points from each cluster. The proportion of error points in each grid cell affiliated with cluster k is determined by the ratio of the number of error points of cluster k to the total number of error points in each grid cell.

Figure respectA1 displays the results of the K-means clustering for non-normalized errors. Table S1 presents the corresponding metrics. Within cluster k=5, the salinity and temperature values closely align with the observations, with a bias of dS=-0.40 g/kg and dT=-0.02 °C, respectively. This cluster encompasses 57 % of all data points. The points are distributed throughout the Baltic Sea and the great majority of them exceed 0.5 (Figure A1b). Clusters k=3 and k=4 exhibit relatively even spatial distributions across the Baltic Sea, accounting for 11 % and 8 % of the points, respectively. These clusters are particularly noteworthy due to their relatively high temperature biases and variability, both of which are crucial for the calculation of marine heatwaves. The clusters k=1 and k=2 represent points with low temperature but a high salinity error (Table A1). Spatially, these points are predominantly located in the southwestern Baltic Sea (Figure A1b), which points to the occasional underestimation or overestimation of the inflow/outflow salinity.

Collectively, approximately 82 % of all validation points exhibit relatively low temperature bias, STD and RMSD (Table A1). The surface-layer validation shows that less than 10 % of comparison points have significant temperature errors (Figure A1c). Due to the low proportion of these validation points, we do not expect a significant impact on the ecosystem in subsurface layersdetermination of surface MHWs and their statistics. Below the surface layer, i.e., at depths ranging from 0.5–40 m, up to 25 % of the points correspond to clusters k=3 and k=4 (Figure A1c). Consequently, we anticipate that the model reanalysis data provides sufficiently accurate information for calculating subsurface MHWs and their statistics for the Baltic Sea.

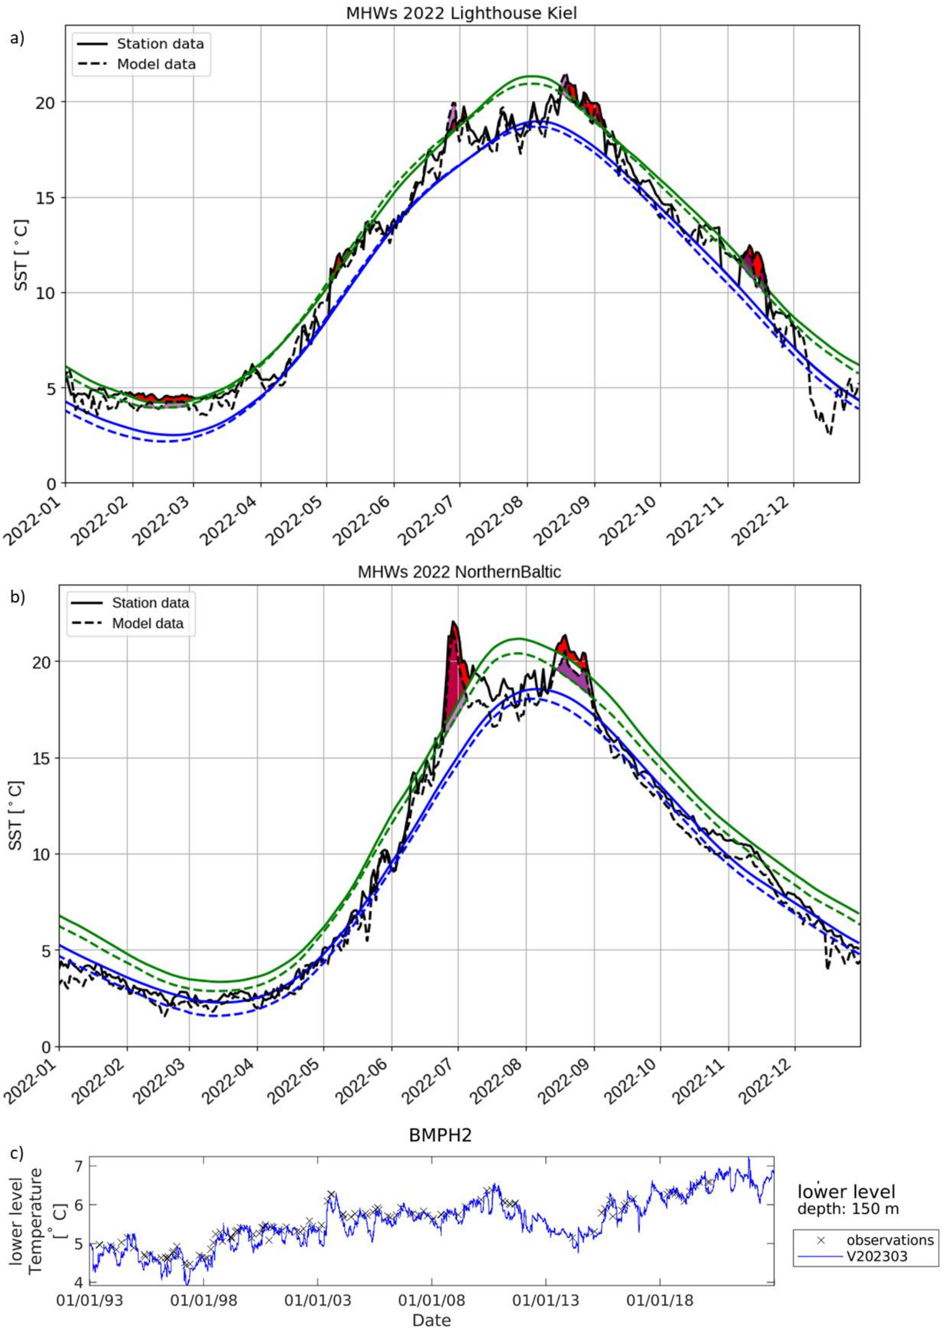

Figure 1: Comparison of station data with model data at (a) LT Kiel (product ref. no. 2 and 3 in Table 1), (b) Northern Baltic (product ref. no. 2 and 3 in Table 1) and (c) BMPH2 (from Panteleit et al., 2023). The dashed lines in (a) and (b) correspond to the model (product ref. no. 3 in Table 1), while the continuous lines correspond to the station data (product ref. no. 2 in Table 1). In blue, the climatological mean is shown. The green lines show the 90th percentile threshold for MHW detection and the black lines are the respective 2022 temperature data. The purple (model data) and red (station data) marked areas show the detected MHWs

~~in 2022. The reference period for LT Kiel (a) is 1993-2021 and 1997-2021 for Northern Baltic (b). (c) shows the validation at the station BMPH2 at a depth of 150 m. The model data is shown in blue and the measured data are displayed with the black crosses.~~

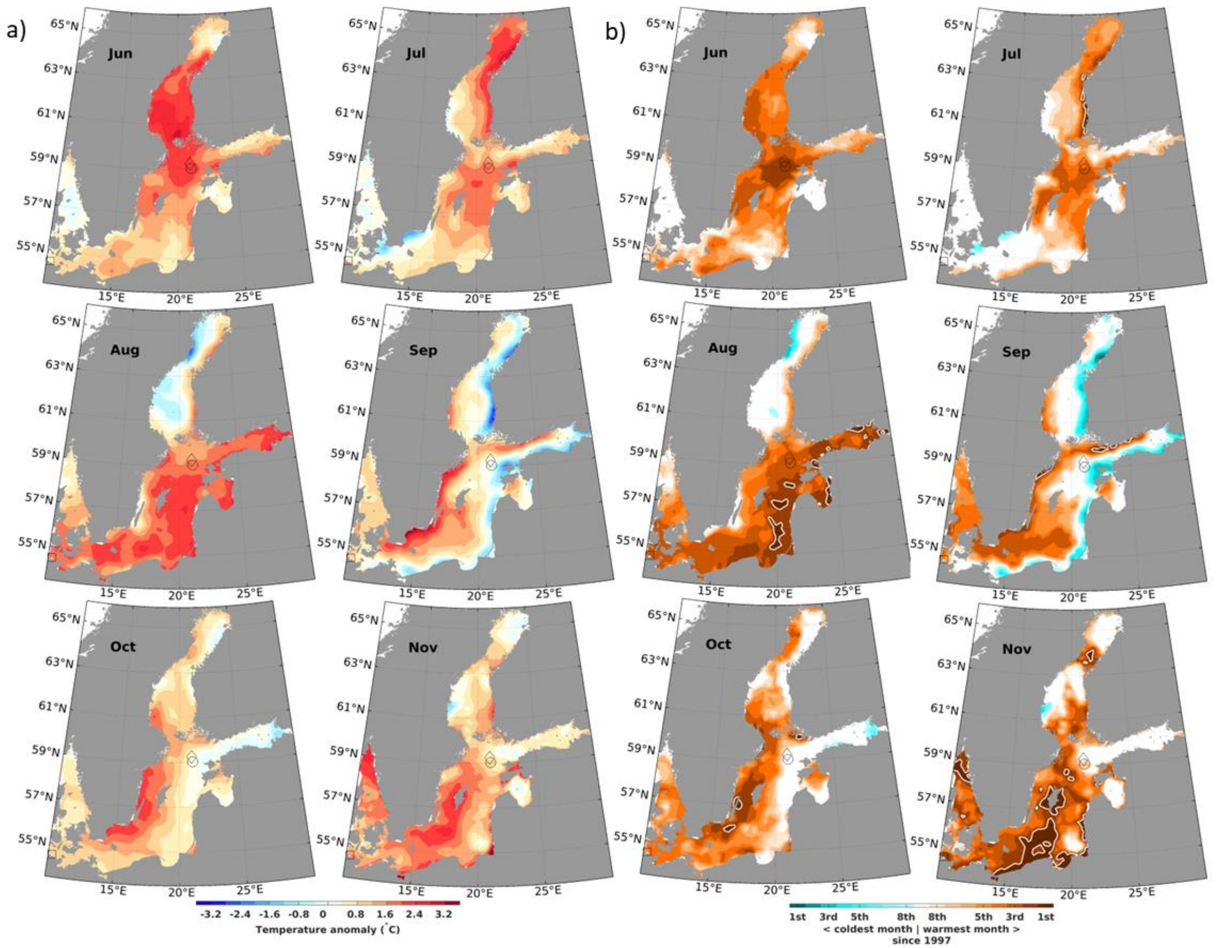

Table 2: Pearson correlation coefficients from linear regression between the MHW metrics computed from the station data and the model data at the stations Lighthouse Kiel and Northern Baltic.

Station	common climatology period	MHW count	MHW max intensity	MHW cumulative intensity	total MHW days
Lighthouse Kiel	1993-2021	0.82	0.88	0.66	0.93
Northern Baltic	1997-2021	0.74	0.89	0.82	0.94

Table 3: Statistical MHW parameter values in various subregions of the Baltic Sea for 2022 based on the model data from the Baltic Sea MYP (product ref. no. 3 in Table 1) using daily values of SST between 1st January 1993 and 31st December 2022. The climatological period covers the years 1993 to 2021.

	Kattegat	Inner Danish Straits	Western Baltic	Baltic Proper	Gulf of Riga	Gulf of Finland	Archipe-lago Sea	Bothnian Sea	Bothnian Bay
Cumulative intensity of longest MHW / °C days	81.5	63.8	64	79.4	63	66.5	61.1	119.3	85.1
Mean intensity / °C	3.6	3.5	3.8	5.3	4.9	5.8	4.5	6.4	6.5
Duration of longest MHW / days	24	29	26	32	17	17	21	31	20
Number of MHWs (modal) per year	1-6 (3)	2-7 (4)	2-7 (5)	1-7 (3)	1-4 (3)	1-4 (2)	2-4 (3)	1-6 (2)	1-5 (2)
Maximum intensity / °C	4.5	4.2	4.6	7.3	5.9	6.8	5.1	8.6	9.6
Total days of MHW conditions / days	56	86	94	79	50	48	55	63	47

Table A1: The share (%), bias, root-mean-square error (RMSE), standard deviation (SD), and correlation coefficient (Corr) for each of the five clusters.

	Shares	Bias		SD		RMSE		Corr		
k	%	dS	dT	dS	dT	S	T	S	T	dSdT
		(g/kg)	(ºC)	(g/kg)	(ºC)	(g/kg)	(ºC)			
1	18.6	-4.14	-0.26	1.80	0.85	4.51	0.89	0.90	0.78	-0.09
2	7.4	3.53	0.39	2.16	1.06	4.14	1.13	0.93	0.75	-0.11
3	10.5	-0.62	2.58	2.12	1.28	2.21	2.88	0.97	0.58	-0.06
4	6.3	0.27	-2.29	1.97	1.21	1.99	2.59	0.95	0.71	-0.14
5	57.2	-0.40	-0.02	0.83	0.54	0.92	0.54	0.99	0.89	0.07

Figures

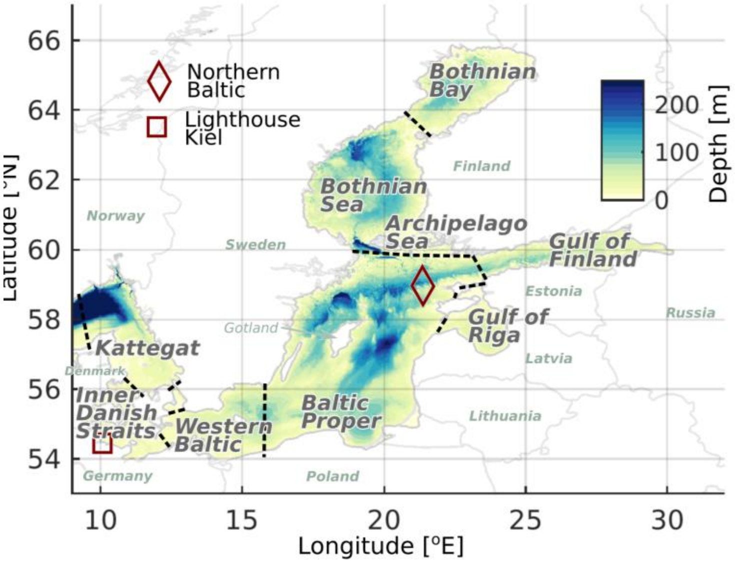

Figure 1: Map of the Baltic Sea with relevant locations mentioned in the study. Boundaries between subregions are marked with dashed lines.

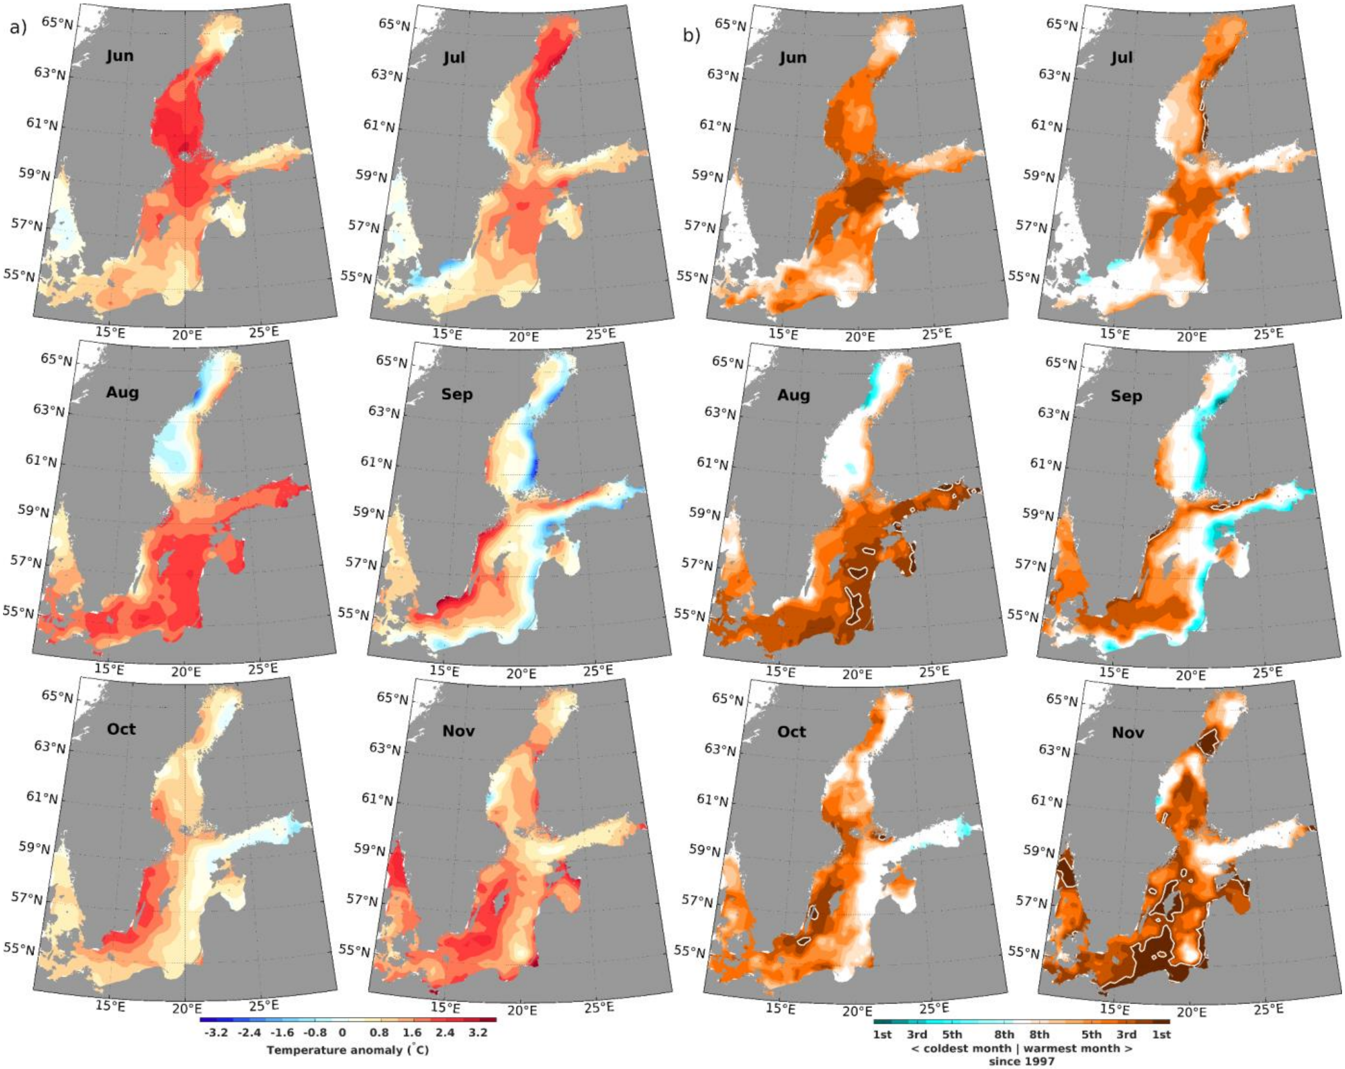

Figure 2:

~~Figure 2:~~ **Anomalies (difference to climatology of 1997-2021) of SST for the Baltic Sea according to the BSH SST analysis (product ref. no 1 in Table 1) during the summer and autumn months in 2022 (a) and ranks of these SST anomalies (b) when compared to the full dataset starting in 1997. In (b), ~~B~~brownish (cyan) colors denote anomalies belonging to the warmest (coldest) eight anomalies found since 1997. Record warm anomalies (rank 1) are highlighted by white contours.** ~~Locations of the in-situ observations discussed in this chapter are marked by a square (LT Kiel), a diamond (Northern Baltic), and a circle (BMPH2), respectively.~~

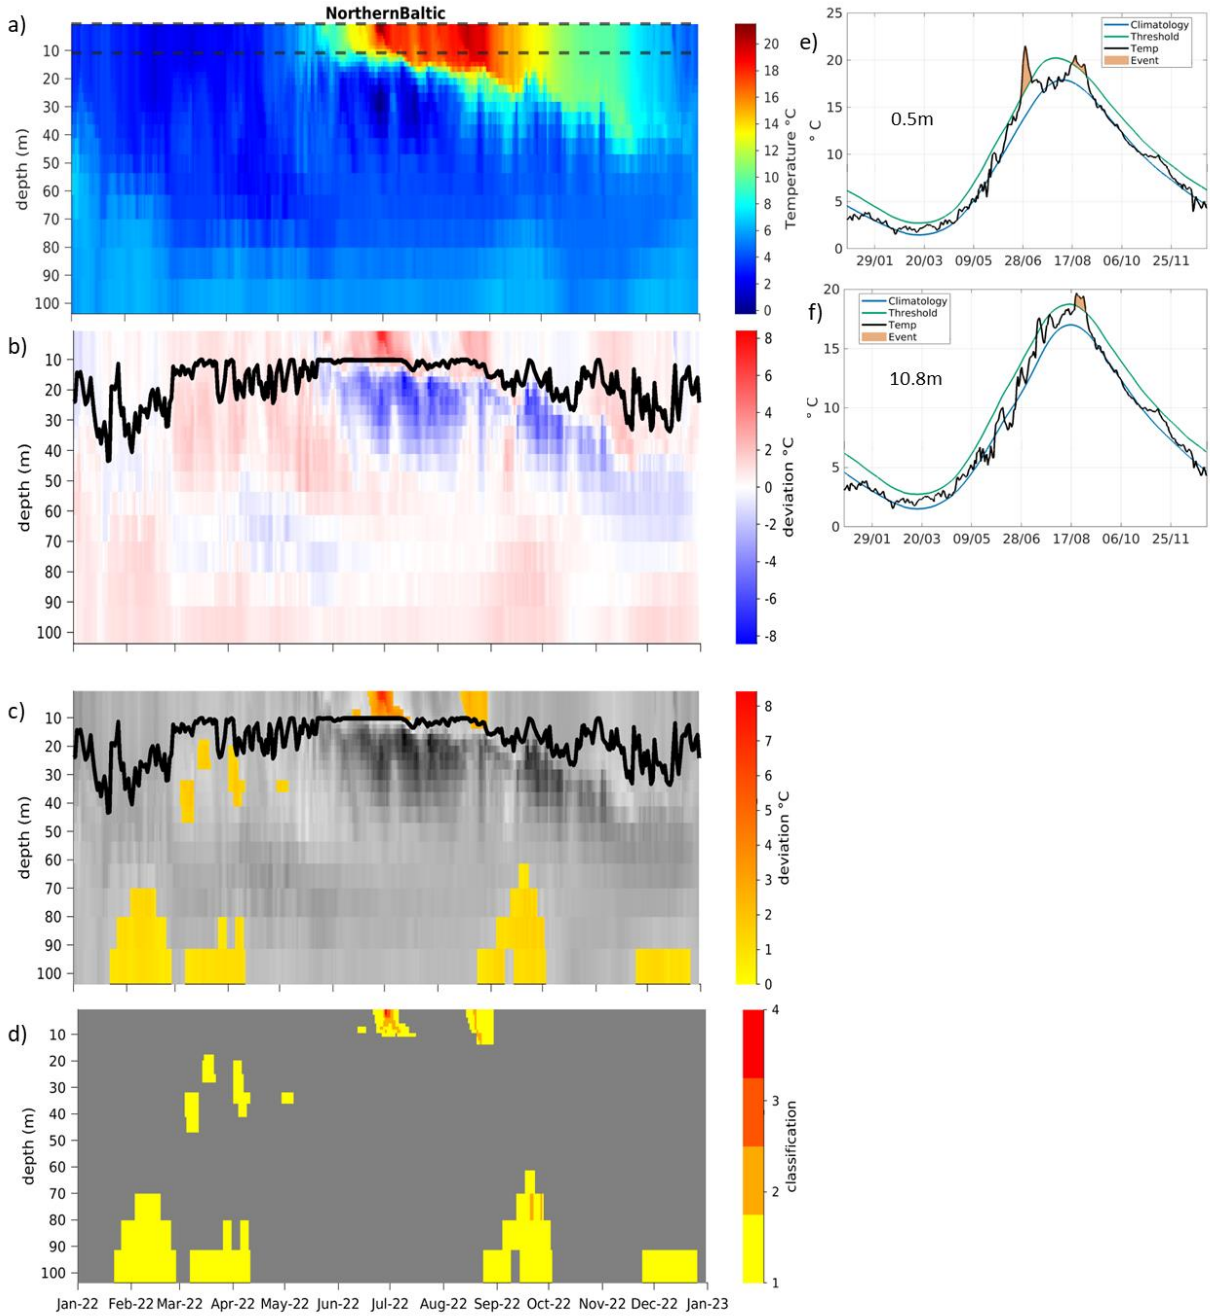

Figure 3~~5~~: Hovmöller diagrams show absolute water temperature (a), temperature ~~anomalies~~deviation between the climatology and the MYP data for 2022 (b) and MHWs (c) and their classifications (d, 1-moderate, 2-strong, 3-severe, 4-extreme) including the mixed layer depth as the thick black line (b and c) at Northern Baltic based on the Baltic Sea MYP (product ref. no. 3 in Table 1). The time series on the right (e-~~h~~f) are located at the vertical positions marked as dashed lines in (a) and show ~~SST~~temperature

(black), climatology (blue), 90th percentile threshold for MHW analysis (green) and MHWs (red shading) based on model data at depths of 0.5 m (e~~),~~) and 10.8 m (f~~), 80.1 m (g) and 103.8 m (h).~~). The period used for the climatology is 1993-2021.

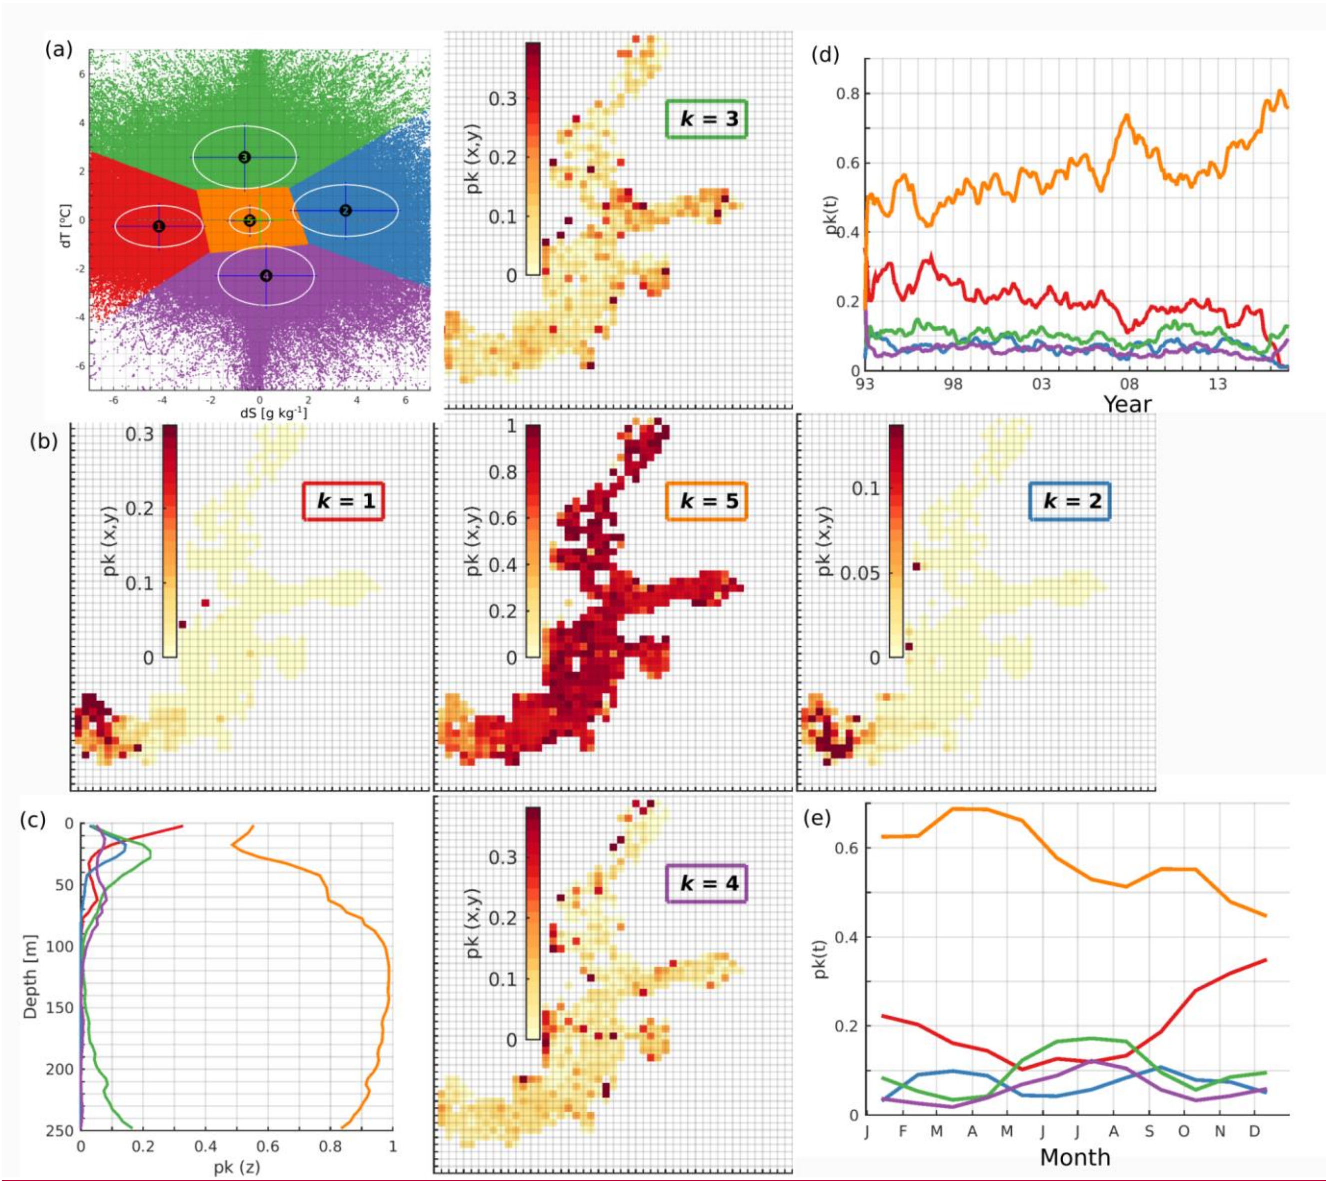

Figure A1: Distribution of normalized error clusters for k=5 (a). The spatial distribution (b, shaded sub-plots), vertical distribution (c), temporal distribution (d), and seasonal distribution (e) of the share of error points belonging to the five different clusters.

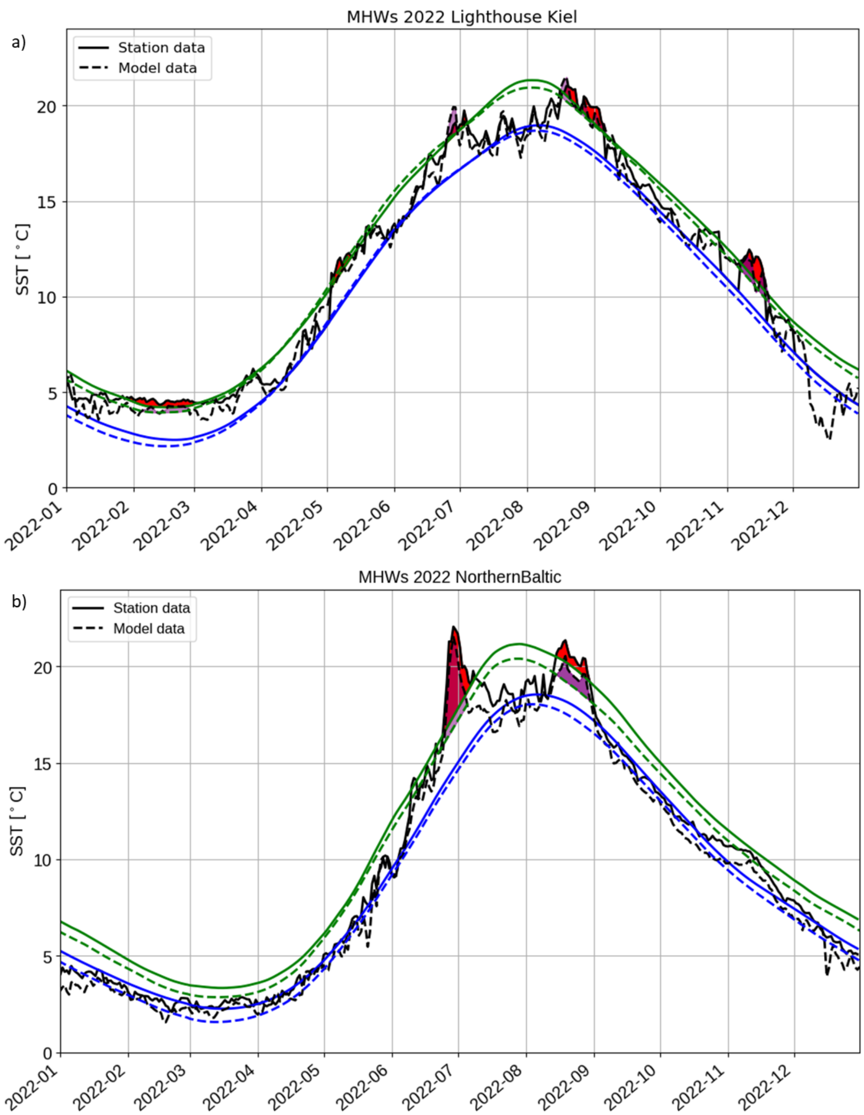

Figure A2: Comparison of station data with model data at (a) LT Kiel (product ref. no. 2 and 3 in Table 1), (b) Northern Baltic (K. Hedi, FMI, pers. communication and product ref. no. 3 in Table 1). The dashed lines correspond to the model, while the continuous lines correspond to the station data. In blue, the climatological mean is shown. The green lines show the 90th percentile threshold for MHW detection and the black lines are the respective 2022 temperature data. The purple (model data) and red (station data) marked areas show the detected MHWs in 2022. The reference period is 1993-2021 for LT Kiel (a) and 1997-2021 for Northern Baltic (b).
