8 **Abstract.** This study presents an improved space geodetic approach to estimate the global ocean heat content (GOHC) change  
9 and the Earth energy imbalance (EEI) over 1993-2022. The EEI exhibits a positive trend of 0.29 W m<sup>-2</sup> decade<sup>-1</sup>, significant  
10 at the 90% confidence level, indicating accelerated ocean warming, in line with independent CERES data. The study highlights  
11 the importance of comparing various estimates (eg. in-situ based GOHC) and their uncertainties, to reliably assess EEI changes.

## 12 1 Introduction

13 The ocean absorbs almost all the excess energy stored by the Earth system that results from the anthropogenic greenhouse gas  
14 emission in the form of heat (~91%; von Schuckmann et al., 2023; Foster et al., 2021). As the ocean acts as a huge heat  
15 reservoir, global ocean heat content (GOHC) is therefore a key component in the Earth's energy budget. An accurate knowledge  
16 of the GOHC change allows us to assess the Earth energy imbalance (EEI), which refers to the difference between the amount  
17 of energy the Earth receives from the sun and the amount of energy it radiates and reflects back into space. A community effort  
18 (Meyssignac et al., 2019) depicted the various methodologies to estimate EEI from the GOHC, including the use of ocean in-  
19 situ temperature and salinity profiles (von Schuckmann et al., 2023), the measurement of the ocean thermal expansion from  
20 space geodesy (Marti et al., 2022; Hakuba et al., 2021), ocean reanalysis (Stammer et al., 2016), and surface net flux  
21 measurements (Kato et al., 2018; L'Ecuyer et al., 2015). Among these approaches, the space geodetic approach, detailed in  
22 Marti et al. (2022), leverages the maturity of satellite altimetry and gravimetry measurements to enable precise, extensive  
23 spatial and temporal coverage, and full-depth estimates of ocean thermal expansion. As the EEI magnitude is small (0.5-1.0  
24 W m<sup>-2</sup>, von Schuckmann et al., 2023) compared to the amount of energy entering and leaving the climate system (~340 W m<sup>-2</sup>  
25 <sup>2</sup>, L'Ecuyer et al. 2015), a high level of precision and accuracy are required to estimate the EEI mean (< 0.3 W m<sup>-2</sup>) and its  
26 time variations at decadal scale (< 0.1 W m<sup>-2</sup>; Meyssignac et al., 2019). In this regard, the space geodetic approach emerges as  
27 a promising candidate capable of meeting the stringent EEI precision and accuracy requirements (Meyssignac et al., 2019;  
28 Marti et al., 2022).

29 In this study, our primary objective is to present the updated space geodetic GOHC and EEI estimates and the improvement  
30 since Marti et al. (2022), including several major evolutions in the input data, algorithms and a temporal extension into the  
31 past, since 1993. The secondary objective is to compare this updated space geodetic monthly GOHC product with GOHC time  
32 series derived from in-situ observations. To ensure a consistent and homogeneous treatment, we apply the same processing  
33 method to estimate the EEI from the different yearly GOHC time series considered. The obtained EEI estimates are then  
34 compared to the net flux at the top of atmosphere (TOA) derived from the Clouds and the Earth's Radiant Energy System  
35 (CERES) mission, which serves as a reference for EEI time variations.

## 36 **2 Data and method**

37 The space geodetic approach consists in deriving the ocean heat content change from the steric sea level change (i.e. the ocean  
38 expansion) inferred by satellite observations. We present here an update of the technique for estimating the GOHC change and  
39 the EEI, which relies on existing work (Marti et al., 2022) but also benefits from the progress made more recently at regional  
40 scales (Rousseau et al., under revision).

41 In accordance with Rousseau et al. (under revision), the GOHC change is obtained as the sum of regional ocean heat content  
42 (OHC) estimated on a  $1^\circ \times 1^\circ$  grid. However, the uncertainties, their characterisation and their propagation from the input data  
43 until the GOHC change and EEI are made at global scale in a similar manner to Marti et al. (2022).

44 Space geodetic observations are consistent with those used in Marti et al. (2022). The total sea level change is derived from  
45 altimetry sea-level gridded products data from the Copernicus Change Climate Change service (C3S) [1]. A correction for  
46 TOPEX-A drift is applied (Ablain et al., 2017) as well as a correction for the Jason-3 radiometer drift (Barnoud et al., 2023).  
47 The manometric sea level change is estimated from an update of Blazquez et al. (2018) gravimetric solution ensemble (V1.6)  
48 [2]. We identified a sub-sample of this ensemble which relies on a single geocenter correction based on Sun et al. (2016) and  
49 whose mean is used as our best estimate of the manometric sea level change.

50 The space geodetic approach builds on the sea level budget to estimate the steric sea level (SSL) change. As we eventually  
51 focus on the GOHC change, we neglect the effect of the halosteric sea level change because the impact of salinity changes on  
52 SSL is very small at global scale (see Appendix of Lowe and Gregory, 2006). The OHC change is obtained from the ratio of  
53 the SSL change and the integrated expansion efficiency of heat (IEEH) coefficient. Knowledge of the warming pattern is a  
54 prerequisite to estimate the IEEH. This knowledge relies on in-situ observations. In previous versions, the IEEH was computed  
55 from in-situ temperature/salinity profiles (mainly Argo floats) (Rousseau et al., under review). Here the IEEH is computed at  
56 regional scale ( $1^\circ \times 1^\circ$ ) from temperature/salinity data from the ECCO ocean reanalysis [3]. Using ECCO to estimate the IEEH  
57 has an advantage as it allows for the expansion of the spatial area used to compute it. It now includes coastal regions up to  
58 100km and deep ocean areas down to 6000m. We have made the approximation that the IEEH is constant over time, and equals

59 to its mean value over 2005-2015. This is justified at global scale because the heat pattern of the ocean does not change  
60 significantly on decadal time scales (Kuhlbrodt and Gregory, 2012).

61 In-situ-derived global IEEH ranges from  $1.36 \cdot 10^{-1} \text{ m YJ}^{-1}$  for a depth down to 2000 m to  $1.57 \cdot 10^{-1} \text{ m YJ}^{-1}$  for a depth down to  
62 6000 m. Using the ECCO ocean reanalysis [3] instead of in-situ data, yields very similar global IEEH values (see Table 1).  
63 Over a larger area the ECCO reanalysis indicates an IEEH of  $1.50 \cdot 10^{-1} \text{ m YJ}^{-1}$ . The global IEEH uncertainty of  $1 \cdot 10^{-3} \text{ m YJ}^{-1}$   
64 ( $[5\%,95\%]$  confidence interval level) is from Marti et al., (2022). It does not account for the IEEH variability due to the spatial  
65 domain.

66 In this study we propose a temporal extension of the space geodetic estimate of GOHC and EEI into the past from January  
67 1993, the start of precise satellite altimetry. As space gravimetry observations are not available before 2002 (GRACE mission  
68 was launched in March 2002), the manometric sea level component is extended into the past with the sum of its individual  
69 contributions from Greenland, Antarctica, glaciers and from terrestrial water storage. These are derived from the ESA climate  
70 change initiative assessment of the sea level budget since 1993 [4].

71 After calculating the GOHC, the EEI is then obtained from the time derivative of the GOHC - by applying a central finite  
72 difference scheme - and accounting for the heat fraction that is entering the ocean (91%) - the remaining 9% of energy being  
73 captured by the atmosphere, land and cryosphere (Forster et al., 2021). As described in Marti et al. (2022), the OHC change  
74 needs to be filtered out beforehand by applying a Lanczos low-pass filter at 3 years to remove signals related to ocean-  
75 atmosphere exchanges which does not correspond to any response to the top of the atmosphere radiation imbalance (Palmer  
76 and McNeall, 2014) and must therefore be removed to infer EEI variations. The following equation summarises how the EEI  
77 is derived from GOHC:

$$78 \quad EEI(t) = \frac{dGOHC_{filtered,adjusted}(t)}{dt} \times \frac{1}{\alpha}, \text{ with } \alpha = 0.91, \quad (1)$$

79 In order to assess the GOHC and EEI estimates, the estimation of their uncertainties is a key point. The method (described in  
80 Marti et al., 2022) consists in calculating the error variance-covariance matrices of the global mean sea level (GMSL) change  
81 data record and of the barystatic sea level data record and then propagating these error variance-covariance matrices to the  
82 GOHC and the EEI estimates. The characterisation of uncertainties is similar to that used by Marti et al. (2022). For the GMSL  
83 uncertainties, we use an updated altimetry uncertainty budget provided by Guérou et al. (2022), mainly extended over the  
84 Jason-3 period (until 2021). For the barystatic sea level uncertainties, we calculate the dispersion of the gravimetry ensemble  
85 [2]. This uncertainty is not centred on the barystatic best estimate (see Figure 1). Besides, an uncertainty on the heat fraction  
86 entering the ocean is introduced ( $[89\%, 93\%]$ ), defined from the different estimates of the literature (e.g. Church et al., 2011;  
87 Levitus et al., 2012; Forster et al., 2021; von Schuckmann et al., 2023). The uncertainty associated with the IEEH once  
88 propagated is negligible compared with other sources of uncertainty on the mean EEI ( $<0.1\%$ ). From the covariance matrices,  
89 we are able to obtain the uncertainty associated with the means, trends or accelerations in GOHC at any time scales, based on  
90 an ordinary least squares regression.

91

92 The space geodetic GOHC and EEI estimates [5] are then compared to other estimates mostly based on in-situ data. First, we  
93 introduce GOHC estimates based on gridded fields of temperature and salinity derived from in-situ measurements, provided  
94 by 5 centres: SIO (Scripps Institution of Oceanography) [6], JAMSTEC version 2021 [7], ISAS20 - IFREMER [8], all three  
95 relying on Argo network data; EN4 using two sets of corrections (Cheng et al., 2014; Gouretski and Cheng, 2020) [9], and  
96 NOAA (National Oceanic and Atmospheric Administration) [10]. We analyse 2 ocean monitoring indicators (OMIs) delivered  
97 by CMEMS [11] and also based on in-situ observations, CORA and hereafter “CORA-2011”, CORA processed by von  
98 Schuckmann and Le Traon (2011). The CORA-2011 dataset is delivered together with an uncertainty envelope whose  
99 estimation is described in von Schuckmann and Le Traon (2011). In addition we compare the space geodetic estimate of the  
100 GOHC to the recent Global Climate Observing System (GCOS) ensemble estimate [12] composed of 16 time series based on  
101 subsurface temperature measurements and representative of the full water column. For the GCOS GOHC ensemble trend we  
102 use the uncertainty indicated in von Schuckmann et al. (2023) for the period 2006-2020. Lastly, we introduce an alternative  
103 full-depth GOHC estimate derived from the space geodetic approach (Hakuba et al., 2021) [13] (hereafter “JPL”), whose  
104 uncertainty is obtained from an ensemble approach.

105 Apart from GCOS ensemble and the space geodetic estimates, the different GOHC change estimates are extended with a deep  
106 ocean warming estimate of  $+0.068 \text{ W m}^{-2}$  from Purkey and Johnson (2010) to encompass the entire water column and account  
107 for the deep ocean's substantial thermal influence below 2000 m. In this way, all different GOHC estimates cover the whole  
108 water column down to the bottom and are thus comparable with each other.

109 Both GCOS ensemble and OMIs are made up of yearly time series, while other estimates are available on a monthly basis,  
110 which restricts comparisons to interannual time scales. Comparisons are thus led on the basis of annual time series, both for  
111 GOHC trend and EEI variability study. The GOHC change estimates are turned into EEI using the same method as described  
112 above, with the only difference that annual time series are linearly interpolated on a monthly time scale beforehand.

113 The CERES Energy Balanced and Filled (EBAF) product [14] is used as a reference for the EEI variability assessment because  
114 it is totally independent and it is known to reproduce precisely the EEI variations with uncertainties of the order of a few tenths  
115 of  $\text{W m}^{-2}$ . Its mean value is anchored with an in-situ product (Lyman and Johnson, 2014).

116 Datasets used for this study are described in Table 2, both for the calculation of GOHC and EEI estimates and for their  
117 intercomparison. All uncertainties are reported in the text with a 5 %–95 % confidence level interval.

### 118 **3 Results**

119 The monthly space geodetic GOHC change from LEGOS-Magellium over January 1993-May 2022 highlights accumulation  
120 of heat in the ocean (86% of the total ocean surface excluding the Mediterranean sea). The trend of  $+0.75 \text{ W m}^{-2}$  provides an  
121 estimate of the global ocean heat uptake (GOHU) and the uncertainty range for this accumulation rate is  $[0.61; 1.04] \text{ W m}^{-2}$   
122 meaning the GOHU is significantly positive over 1993-2022.

123 A comparison is made with the annual GOHC change time series from GCOS (Figure 1). The heat content is an extensive  
124 variable and GOHC is therefore highly sensitive to spatial coverage. To ensure more consistency in comparison with GCOS,  
125 we constrained the LEGOS-Magellium dataset to an ocean surface comparable to GCOS (up to 60° latitude and for areas more  
126 than 300m deep). The impact was found to be low with a trend of 0.73 W m<sup>-2</sup> over 1993-2022. Despite a higher value for the  
127 LEGOS-Magellium dataset, the trend results for 1993-2020 are in agreement within their confidence intervals, with the GCOS  
128 trend of 0.60 [0.39; 0.82] W m<sup>-2</sup> and the LEGOS-Magellium trend of 0.71 [0.58, 0.99] W m<sup>-2</sup>.

129 When the GOHC trends are calculated over a shorter period (2005-2019) on their respective available ocean surface (Figure  
130 2), the conclusions are similar to those in Figure 1. GOHC trend results from other estimates are also shown. Note that the  
131 GCOS ensemble encompasses CORA and CORA-2011 datasets as well as solutions based on the same in-situ temperature and  
132 salinity grids that are used and mentioned in section 2. In general, GOHC estimates exclusively based on in-situ measurements  
133 are in agreement within their uncertainty ranges. These estimates are constructed using the same atlas of temperature and  
134 salinity profiles. Specifically, the data used to calculate the 5 GOHC from gridded fields covers the same ocean surface. Despite  
135 this, their trends show some discrepancies that are due to the data processing such as the selection of valid profiles and gridding  
136 algorithm. The comparisons confirm that the LEGOS-Magellium dataset shows a stronger trend in GOHC than datasets relying  
137 on in-situ measurements, but still agrees within the 90% confidence level. The JPL space geodetic estimate supports these  
138 results and increases our confidence in our method.

139  
140 Temporal variations of the EEI derived from the monthly LEGOS-Magellium space geodetic dataset agree well with the direct  
141 EEI measurements provided by CERES but less so with the EEI derived from the GCOS yearly ensemble (Figure 3). Correlated  
142 signals are observed, particularly after 2006. These interannual variations are related to the main coupled ocean-atmosphere  
143 climate modes modes such as El Niño or the Pacific Decadal Oscillation (Loeb et al. 2018, Meyssignac et al., 2023) or the  
144 atmospheric aerosol content resulting from volcanic eruptions and anthropogenic emissions. The 3 EEI solutions show a trend  
145 over their respective periods: 0.29 [0.04;0.56] W m<sup>-2</sup> decade<sup>-1</sup> for LEGOS-Magellium over 1993-2022; 0.17 W m<sup>-2</sup> decade<sup>-1</sup> [-  
146 0.25;0.60] for GCOS over 1993-2020; 0.44 [0.34; 0.55] W m<sup>-2</sup> decade<sup>-1</sup> for CERES over 2000-2022. Over the common period  
147 2000-2020, the LEGOS-Magellium dataset shows a positive trend of 0.37 W m<sup>-2</sup> decade<sup>-1</sup> in agreement with CERES EEI trend  
148 of 0.44 W m<sup>-2</sup> decade<sup>-1</sup> and both trends are significant at the 90% confidence level. Given the confidence intervals and good  
149 agreement between these independent datasets, these results provide confidence in the observed trend in EEI since 2000,  
150 indicating a very likely acceleration in global ocean warming over 2000-2020.

151 The Taylor diagram in Figure 4 indicates the similarity in terms of temporal variability between all OHC-based EEI and the  
152 CERES reference. The dataset's proximity to the blue star determines the degree of agreement and how well it matches CERES  
153 estimate of the EEI variability. The GCOS and LEGOS-Magellium products exhibit similar time variations, with a correlation  
154 of approximately 0.7, which is comparable to the results of Loeb et al. (2021). The JPL EEI has the highest correlation with  
155 CERES data (0.9), but too much variability. In-situ-based products have a correlation range of 0.25 to 0.8, indicating different  
156 levels of agreement with CERES.

## 157 **4 Discussions and conclusions**

158 This study proposes an extended estimate of the GOHC change and the EEI from 1993 onwards using the space geodetic  
159 approach. We compare this estimate with various estimates based on in-situ measurements, as well as with the CERES EBAF  
160 estimate of the EEI.

161 Apart from the global measurement by CERES, the studied methods do not yet cover the entire ocean. However, the major  
162 advantage of the space geodetic approach is the large and homogeneous sampling of the ocean surface since August 2002, and  
163 the integration of the whole water column. The space geodetic GOHC shows a significant trend of  $+0.75 [0.61;1.04] \text{ W m}^{-2}$   
164 and EEI trend of  $0.29 [0.04;0.56] \text{ W m}^{-2} \text{ decade}^{-1}$  over the period 1993-2022.

165 Considering the current knowledge of the uncertainties associated with satellite gravimetry and altimetry data, the comparison  
166 of our results with other datasets allows us to cross-check the consistency of the different estimates of the ocean warming rate  
167 within a [5%-95%] confidence level interval. However, the higher GOHC trends observed with the space geodetic approach  
168 (LEGOS-Magellium and JPL datasets) compared to all in-situ datasets could reveal limitations in the observing systems such  
169 as the unobserved deep ocean with in-situ data or systematic errors in space geodetic data, which need to be further  
170 investigated.

171 In addition, the comparison of our space geodetic EEI estimate with the direct EEI estimates provided by the CERES EBAF  
172 dataset provides complementary assessment information on the variability of EEI. On the one hand we find a good temporal  
173 correlation of the EEI derived from space geodetic and CERES EBAF estimates. On the other hand a significant EEI trend has  
174 been detected in both CERES and the space geodetic approach suggesting a very likely acceleration of global ocean warming  
175 over the last 20 years.

## 176 **Data availability**

177 Space geodetic GOHC change and EEI dataset (v5.0) is available online at <https://doi.org/10.24400/527896/a01-2020.003>  
178 (Magellium/LEGOS, 2020) with the complete associated documentation (product user manual and algorithm theoretical basis  
179 document).

## 180 **Acknowledgements**

181 We would like to first thank Audrey Minière, Karina Von Schuckmann and Lorena Moreira Mendez for their contributions to  
182 the preparation of this paper and Françoise Mertz for making the data available on the ODATIS portal and AVISO. We also  
183 thank two anonymous reviewers for their constructive comments on earlier drafts of this manuscript.

184 **Financial support**

185 This work has been supported by CNES, both for its development and dissemination. Comparison with other datasets was  
186 funded by CNRS. ESA initially supported this work in the framework of the MOHeaCAN project (Monitoring Ocean Heat  
187 Content and Earth Energy ImbalANce from Space): <https://eo4society.esa.int/projects/moheacan/> (last access: 20 December  
188 2023).

346 **Figure 1: Global ocean heat content change over 1993-2022 depicted by the LEGOS-Magellium space geodetic dataset (red curve)**  
347 **and the GCOS dataset available until 2020 (purple curve). The LEGOS-Magellium dataset is characterised by its standard**  
348 **uncertainty envelope (68% confidence level). The ocean surface considered for the LEGOS-Magellium dataset is comparable to that**  
349 **of the GCOS ensemble (von Schuckmann et al., 2023). Trends are estimated at 5-95% confidence interval level and refer to the top-**  
350 **of-atmosphere surface.**

351

352

353  
354  
355  
356

**Figure 2: Global ocean heat content (GOHC) trends over the period 2005-2019 from the LEGOS-Magellium (red) and JPL (blue) space geodetic datasets, the GCOS ensemble (purple), in-situ-based GOHC change time series (brown tones), and the 2 CMEMS indicators (green tones). Trends are computed from annual time series and refer to the top-of-atmosphere surface and the indicated trend intervals correspond to the [5-95%] confidence interval level.**

357  
358

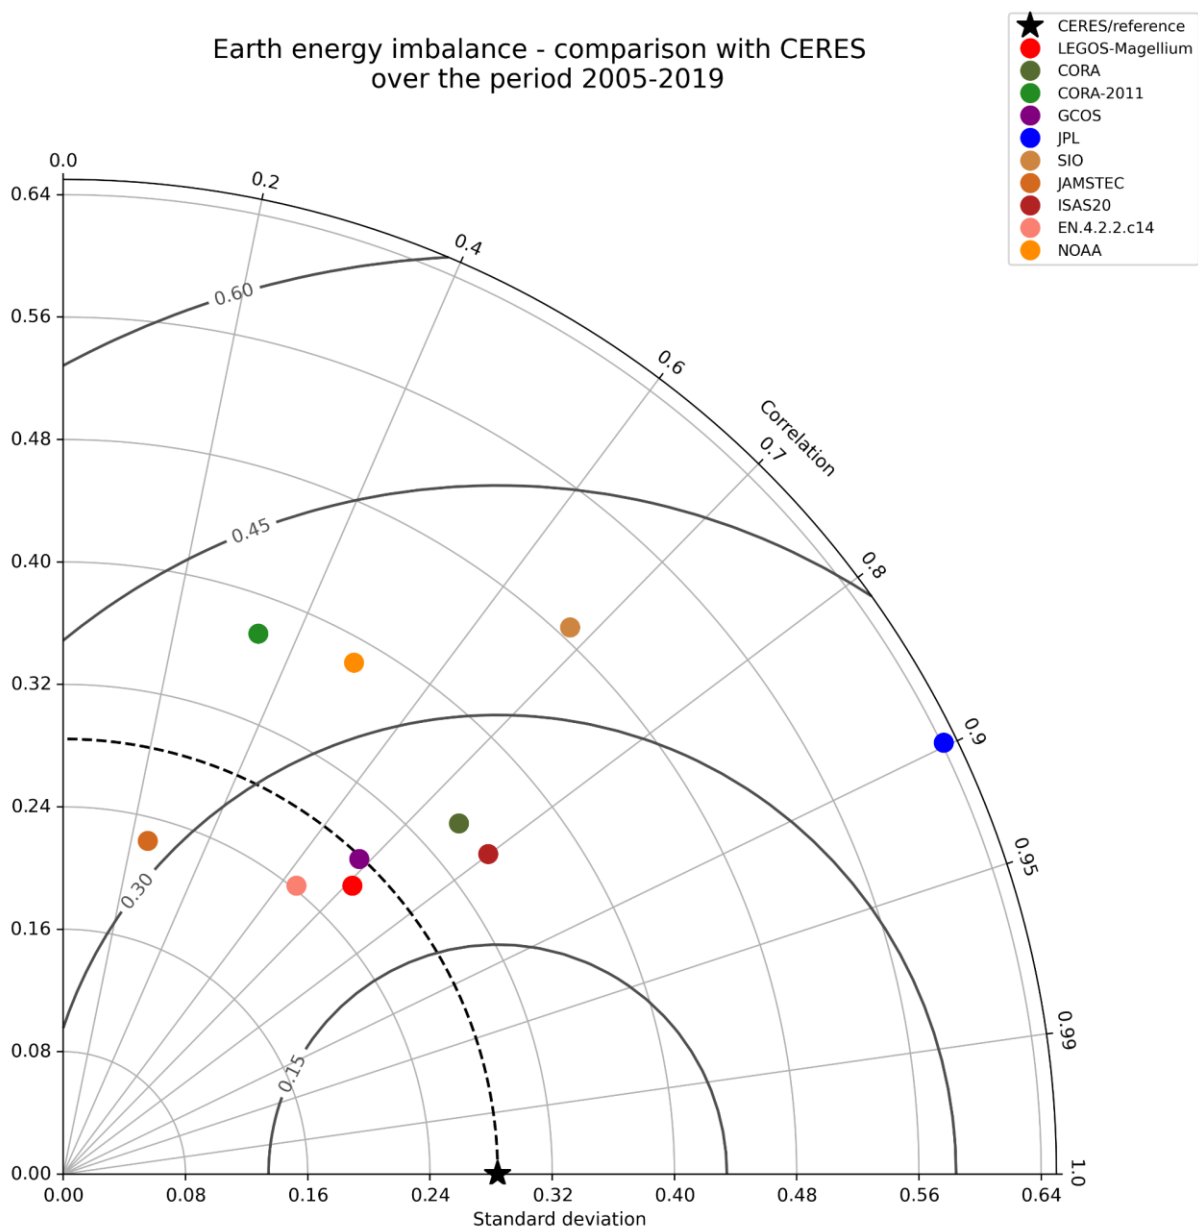

359 **Figure 3: Earth energy imbalance (EEI) time series derived from the LEGOS-Magellium space geodetic approach (red curve),**  
360 **GCOS dataset (purple curve) and from satellite CERES measurements (black curve) over 1993-2022. A 3-year filter is applied to**  
361 **the space geodetic GOHC before derivation into EEI. CERES time series is also filtered at 3 years for comparison. Standard**  
362 **uncertainty envelope (68% confidence level) is shown for the space geodetic dataset in light red. EEI trends are given for each dataset**  
363 **on their common availability period 2000-2020 and refer to the top-of-atmosphere surface. Uncertainties are estimated with a [5%-**  
364 **95%] confidence interval level.**

365

366

367 **Figure 4: Comparison of Earth energy imbalance (EEI) interannual variations with respect to the CERES dataset (black star) on**  
 368 **the 2005-2019 period. Taylor diagram gathering the correlation Pearson coefficient, the centred root means square ( $W m^{-2}$ ) and the**  
 369 **standard deviation ( $W m^{-2}$ ) for the LEGOS-Magellium (red), JPL (blue), GCOS (purple), in-situ-based EEI (brown tones), and**  
 370 **CMEMS indicators (green tones). Results refer to the top-of-atmosphere surface.**
