**Abstract.** Regional variations of the mass component of sea level (manometric sea level) are intimately linked with the changes in the water cycle, volume transports, and inter-basin exchanges. Here, we investigate the consistency at the regional level of  
15 the manometric sea level from the Copernicus Marine Service global reanalyses and compare with observation-based products, deduced from either gravimetry (GRACE missions) or altimetry and in-situ ocean observations (sea level budget approach, SLB), for some climate-relevant diagnostics such as interannual variability, trends, and seasonal amplitude. The analysis is performed for three basins (Mediterranean Sea; Arctic, and North Atlantic Oceans), and indicates very different characteristics across the three. The Mediterranean Sea exhibits the largest interannual variability, the Arctic Ocean the most pronounced  
20 seasonal cycle, and the North Atlantic a nearly linear increase that is well explained by global barostatic sea level variations. The three datasets show significant consistency at both the subannual and the interannual time scales, although differences in linear trends are sometimes significant (e.g., GRACE overestimates the trend in the Arctic and underestimates it in the Mediterranean Sea, compared to the other products). Furthermore, GRACE and GREP prove mutually more consistent than with respect to the SLB in some cases, i.e., in the Arctic Ocean (all scales) and in the Mediterranean Sea (subannual scale).  
25 Finally, we analyze the main modes of variability for the selected ocean basins and link them with large-scale modes of climate variability; the North Pacific Gyre Oscillation, the Arctic Oscillation, and the Atlantic Multidecadal Oscillation are proven to be the most influential modes for the North Atlantic Ocean, Mediterranean Sea, and Arctic Ocean manometric sea level, respectively.

30 **Short summary.** The variability of the manometric sea level (i.e., the sea level mass component) in three ocean basins is investigated in this study using three different techniques (reanalyses, gravimetry, and altimetry in combination with in-situ observations). We identify the emerging long-term signals, the consistency of the datasets, and the influence of large-scale climate modes on the regional manometric sea level variations at both subannual and interannual time scales.

## 35 **1 Introduction**

Contemporary changes in global sea level at the interannual timescale are driven mostly by two contributions: the changes in the density-driven variations of sea level, the so-called steric sea level that responds to the expansion and contraction of seawater due, mostly, to increasing heat in the oceans (Storto et al., 2019a). The other contributor to global sea level change is the ocean mass change, called barystatic sea level (Gregory et al., 2019). Barystatic sea level has been recently found to be responsible for the majority (about 60%) of the global sea level changes, (Frederikse et al., 2020; Fox-Kemper et al., 2021). Recent estimates indicate  $2.25 \pm 0.16 \text{ mm yr}^{-1}$  of sea level rise due to barystatic changes for the recent period (2005-2016) (Amin et al., 2020). Changes in barystatic sea level are due to the loss of mass from glaciers and ice sheets (Greenland and Antarctica) and from changes in the global water cycle and land water storage. As such, barystatic sea level changes are a fundamental proxy of climate change and are expected to increase even more dramatically in the future, due to increased ice melting according to future projections (Oppenheimer et al., 2019).

At the regional scale, local dynamics, and regional hydrology, together with cross-basin exchanges, modulate regional ocean mass exchanges, called manometric sea level (Gregory et al., 2019). For instance, Camargo et al. (2022) show that regional trends in manometric sea level may vary from  $-0.4$  to  $3.3 \text{ mm yr}^{-1}$  across the global ocean for the 2003-2016 period. Typically, regions characterized by high dynamic variability are characterized by large manometric variations. Strong climate modes of variability (e.g., the North Atlantic Oscillation) are also responsible for large deviations in manometric sea level (e.g., Criado-Aldeanueva et al., 2014; Volkov et al., 2019); fingerprinting techniques can be used to estimate the influence of a specific climate index on the resulting sea level variability (e.g., Pfeffer et al., 2022). In the Mediterranean Sea, for instance, variations are intimately linked to the exchanges with the Atlantic Ocean through the Gibraltar Strait, and variations in the atmospheric freshwater input, which are both strongly linked to North Atlantic variability (e.g., Tsimplis and Josey, 2001).

Since 2002, methods to observe and analyze manometric and barystatic sea level variations have generally relied on GRACE (Gravity Recovery And Climate Experiment; e.g. Tapley et al., 2004) and GRACE-FO (GRACE-Follow On; Landerer et al., 2020) satellite mission measurements of the temporal and spatial variations of the Earth's gravity field. Barystatic and manometric sea level signals can also be inferred from the difference between total sea level, measured by altimetry missions, and steric sea level, estimated through in-situ observations (e.g., Horwath et al., 2022). This approach will be referred to as the Sea Level Budget (SLB) method in the remainder of this article.

Alternatively, ocean general circulation model (OGCM) simulations embed the variability of sea level and its components, although they significantly lack realism (e.g., Kohl et al., 2007). Ocean reanalyses, which combine an ocean model with observations through data assimilation (Storto et al., 2019b) are in turn able to provide a good estimation of the sea level variability at global and basin scales (e.g., Storto et al., 2017); they are thus complementary to gravimetry based and sea level budget based observational counterparts and can be used for a number of investigations (e.g., Peralta-Ferriz et al., 2014; Marcos, 2015; Hughes et al., 2018). A few limitations in the use of reanalyses exist, though. First, the usual Boussinesq approximation in the OGCMs leads to a zero global steric sea level by construction, as the models cannot represent the steric expansion and contraction in the constant volume framework. However, the global steric sea level can be computed and added to the model sea surface height retrospectively, since it does not have any dynamical signature (e.g., Greatbatch, 1994).

A more critical and long-standing issue in reanalyses regards the barystatic and manometric sea level components. Indeed, both the use of climatological freshwater input from land and ice and the imbalance of the atmospheric freshwater forcing combined with the evaporation and sublimation calculated by the ocean model make barystatic and manometric terms often unrealistic. Some reanalyses correct the barystatic sea level with globally uniform offsets, either time-varying or constant. In any case, the barystatic signal is generally unrealistic, and the manometric one may be affected by inaccuracies in the freshwater input into the oceans. In general, ocean bottom pressure data derived from gravimetry could also be directly assimilated into ocean models (see e.g., Köhl et al., 2012). However, this approach was found suboptimal, mostly due to the

low signal-to-noise ratio of the gravimetry data compared to altimetry data assimilation (e.g., Storto et al., 2011), and their issues related to the pre-processing (persistent stripes and land water leakage). Finally, the limited spatial resolution of the models may limit the representativeness of sea level variations in mesoscale active areas (e.g., Androsov et al., 2020).

80 The goal of this paper is manifold. First, we aim to estimate the consistency of estimates of manometric sea level from notably different approaches, which use numerical ocean models, gravimetry or altimetry, and in-situ observations. These approaches are known to contain different sources of uncertainty and none of them is fully trustable, as discussed in detail in this and the next sections. By doing so, we can rank the diagnostics, and areas, showing the largest consistency and, hence, confidence. Particular attention will be devoted to assessing whether the latest generation of the Copernicus Marine Service global  
85 reanalyses is able to capture the interannual variations of the manometric sea level. Second, we aim at assessing the multi-method mean signal, quantifying regional trends and amplitudes, to identify the emerging levels and scales of manometric sea level variability depending on the specific basin. Finally, we aim to fingerprint the manometric sea level with several climate mode indices, to connect such variations with large-scale climate variability.

The structure of the paper is as follows: we compare regionally (section 3) the manometric sea level from reanalyses with those  
90 coming from satellite gravimetry or the sea level budget approach (described in section 2). The exercise will therefore provide an indication of the consistency of the reanalyses and observation-based products for selected metrics. Finally, we summarize and conclude (section 4).

## 2 Data and Methods

In this section, we shortly introduce the datasets used in the assessment. We refer to Gregory et al. (2019) for the terminology  
95 and definitions used to characterize the sea level components.

### 2.1 Gravimetry-based dataset

Barystatic and manometric sea level anomalies have been estimated from April 2002 to August 2022 at a monthly timescale and with a spatial resolution of  $1^\circ$  using an ensemble of GRACE and GRACE-FO solutions (Product ref. no. 2 in Table 1). The GRACE and GRACE-FO ensemble is constituted of 120 solutions, allowing us to estimate the uncertainties associated  
100 with different processing strategies and geophysical corrections needed for ocean applications. The ensemble is based on coefficients of the Earth's gravitational potential anomalies estimated by five different processing centers (CNES, CSR, JPL, GFZ, ITSG). A large variety of post-processing corrections are applied to the ensemble, including two geocenter motions (Lemoine and Reinquin, 2017; Sun et al., 2016), three oblateness values (C20) of the Earth (Cheng et al., 2013; Lemoine and Reinquin, 2017; Loomis et al., 2019), and two Glacial Isostatic Adjustment (GIA) corrections (Peltier et al., 2015, Caron et  
105 al., 2018). To reduce the anisotropic noise, characterized by typical stripes elongated in the North-South direction, decorrelation filters, called DDK filters (Kusche et al., 2009), are applied to GRACE solutions, using two different orders (DDK3 and DDK6) corresponding to different levels of filtering. The ensemble of 120 solutions results from the combination of these five processing centers, two geocenter models, three oblateness models, two GIA corrections, and two filters. The ensemble standard deviation provides a measure of uncertainty for both the barystatic and manometric sea level timeseries.

### 110 2.2 Sea level budget-based dataset

The estimation of barystatic and manometric sea level changes is extended to the altimetry era (January 1993 - December 2020) using the sea level budget approach (Product ref. no. 3 in Table 1). The manometric sea level changes are calculated as the difference between the geocentric sea level changes based on satellite altimetry and steric sea level changes based on in situ measurements of the seawater temperature and salinity. The barystatic sea level changes are computed as the difference

115 between the global mean geocentric sea level changes and thermosteric sea level changes to avoid drifts due to Argo salinity measurement errors (Barnoud et al., 2021; Wong et al., 2020).

Geocentric sea level changes are estimated using the vDT2021 sea level product provided by the Copernicus Climate Change Service (C3S; Legeais et al., 2021). Geocentric sea level changes are corrected for the drifts in Topex-A altimeter (Ablain, 2017) and Jason-3 microwave radiometer wet troposphere correction (Barnoud et al., 2023a, 2023b), for the GIA effect, using the ensemble mean of 27 GIA models (Prandi et al., 2021) centered on ICE5G-VM2 (Peltier et al., 2004), and for the elastic deformation of the solid Earth due to present-day ice melting (Frederikse et al., 2017). The uncertainty of the geocentric sea level changes is calculated with the uncertainty budget and method detailed in Guérou et al. (2023) for the global mean sea level changes and in Prandi et al. (2021) for the local sea level changes.

120 Steric sea level changes are estimated as the sum of the thermosteric and halosteric sea level changes calculated from gridded temperature and salinity estimates from three different centers including EN4 (Good et al., 2013), IAP (Cheng et al., 2020) and Ishii et al. (2006). EN4 provides four datasets with different combinations of corrections for XBT and MBT measurements applied, leading to an ensemble of 6 temperature and salinity datasets. From these datasets, we compute the thermosteric and halosteric sea level changes due to temperature and salinity variations between 0 and 2000 m depth. A linear trend of  $0.12 \pm 0.03 \text{ mm yr}^{-1}$  is added to consider the contribution of the deep ocean to thermosteric sea level changes (Chang et al., 2019).

125 Steric sea level changes are estimated as the ensemble mean of the 6 solutions, and their uncertainties are estimated with the covariance matrix of the ensemble.

The resulting barystatic and manometric uncertainties are described by the covariance matrix obtained by summing the sea level and steric covariance matrices.

### 2.3 The reanalysis dataset

135 In this work, we use the Global Reanalysis Ensemble Product (GREP) from the Copernicus Marine Service (Product ref. no. 1 in Table 1), which is a small-ensemble global reanalysis product, including in turn the four reanalyses i) CGLORS (v7) from CMCC; ii) GloSea5 from UKMO; iii) GLORYS2 (V4) from Mercator Ocean, and iv) ORAS5 from ECMWF. All reanalyses are performed using the NEMO ocean model (Madec et al., 2017) configured at about  $1/4^\circ$  of horizontal resolution and 75 levels. However, the four reanalyses differ for several issues, which can be summarized in the i) NEMO model version and a few selected parametrizations, including specific choice in the use of the ECMWF reanalysis (ERA-Interim and ERA5) atmospheric forcing; ii) initial conditions at the beginning of the reanalyzed period, which covers from 1993 to 2019 and is being updated in delayed time mode; iii) the data assimilation scheme, and iv) the set of observations assimilated, including their source and pre-processing procedures. Thus, GREP can span to a good extent the uncertainty linked with model physics and input datasets. We have used monthly mean data at  $1/4^\circ$  of horizontal resolution for the comparison described in the following section. More details of the four reanalyses together with some in-situ-based validation and assessment of the ensemble standard deviation are provided by Storto et al. (2019c).

140 The estimation approach for GREP follows that of the sea level budget approach (see section 2.2), where the manometric sea level is calculated as a difference from the total sea surface height anomaly from the reanalysis, and the steric sea level anomaly, calculated from the reanalysis output temperature and salinity fields. Thus, we can cross-compare GREP data with GRACE and SLB datasets in terms of interannual variability, trend, and seasonal amplitude.

### 2.4 Analysis methods

Basin-averaged timeseries are analyzed in the next section as monthly means to assess the main variability signal over three oceanic basins (the Arctic Ocean, defined as the region covering from  $67^\circ\text{N}$  in the Atlantic to the Bering Strait; the North Atlantic Ocean, defined from  $0^\circ\text{N}$  to  $67^\circ\text{N}$ ; the Mediterranean Sea). Timeseries are also analyzed in terms of their interannual

155 and subannual signal, where the interannual signal is the timeseries to which the monthly climatology has been subtracted, and  
the subannual the residual part. The uncertainty of the timeseries corresponds to that provided by the dataset (which in turn  
uses an ensemble approach to estimate uncertainty as ensemble standard deviation); by construction, GREP, with only four  
members, is known to underestimate the uncertainty of the manometric sea level (Storto et al., 2019c). Uncertainty of trends  
is estimated through bootstrapping (Efron, 1979) and closely resembles the estimates calculated following Storto et al. (2022).  
160 Explained variance, as percent  $R^2$  coefficient, is used to quantify how much of the regional signal is explained by the global  
barystatic signal due to fast barotropic motion. For this analysis, we show only GRACE and SLB, because the GREP barystatic  
sea level is either unreliable due to drifts in the freshwater forcing, or it is adjusted to GRACE-derived data and, thus, is not  
independent. Seasonal amplitude is defined by fitting to a sinusoidal curve, while interannual variability is the standard  
deviation of the detrended and deseasonalized timeseries. Percents of manometric sea level trends over the total sea level ones  
165 are calculated from the Copernicus Marine Service dataset (Product ref. no. 4 in Table 1), over each region.  
LASSO regression (Tibshirani, 1997), performed between the normalized manometric sea level and normalized climate  
indices, is a regularization technique for multivariate regression, which is used in this study to rank the influence of the climate  
indices on the basin-averaged manometric sea level, in a way like what Pfeffer et al. (2022) proposed. After performing k-fold  
cross-validation (with 10 folds) to identify the best hyperparameters, LASSO regression avoids overfitting the regression, such  
170 that absolute values of the regression coefficients quantify the impact of a predictor on the manometric sea level. We also  
verified that other methods (e.g., the  $R^2$  hierarchical decomposition from Chevan and Sutherland, 1991) provide the same  
results. For these analyses, the *glmnet* (Friedman et al., 2010) and *relaimpo* (Groemping, 2006) R packages are used. Finally,  
for the statistical significance of the correlations and their differences, we used the *psych* R package (Revelle, 2023) that  
implements Steiger's test for comparing dependent correlations (Steiger, 1980; Olkin and Finn, 1995). All statistical  
175 significance results are provided at the 99% confidence level.

### 3 Results

We present the results of the assessment, by first analyzing the timeseries and several diagnostics of the basin-averaged  
manometric sea level; then, the consistency between the manometric sea level products is addressed; finally, the influence of  
the climate modes of variability on the manometric sea level variability is analyzed.

#### 180 3.1 Manometric sea level timeseries

The monthly means of the manometric sea level for the three basins considered in this study is shown in Figure 1, while several  
diagnostics (trend, seasonal amplitude, interannual variability, and mean uncertainty) are provided in Table 2, for the three  
datasets considered.

The three basins (Arctic Ocean, North Atlantic Ocean, and Mediterranean Sea) exhibit significantly different behavior;  
185 GRACE, SLB, and GREP show, however, qualitatively good consistency in all three seas. The Arctic Ocean has a regular  
periodicity and a large seasonal amplitude, with a generally increasing yearly mean signal, except during the first years of the  
timeseries (2003-2005). For both GRACE and GREP, the latest years are the ones with the largest manometric sea level, which  
is reflected in large trends ( $2.45 \pm 0.45$  and  $6.19 \pm 0.87$  mm yr<sup>-1</sup>, respectively) compared to the other seas, while SLB shows a  
weak trend. The consistency with the global barystatic signal at the interannual timescale is not large and quite different  
190 between GRACE (45%) and SLB (2%), meaning that internal dynamics, straits connections, and the sea-ice seasonal cycle  
significantly modulate the regional manometric sea level. Note that the GRACE-derived trend is likely too large, as it exceeds  
the altimetry-based total sea level trend of 2.9 mm yr<sup>-1</sup>, although the latter is characterized by significant under-sampling at  
high latitudes and ice-covered regions.

195 The North Atlantic manometric sea level signal has a pronounced seasonality (4.2 to 13.5 mm, depending on the dataset), the  
smallest interannual variability (6.6 to 8.6 mm), and a nearly-linearly increasing mean signal. The percent explained variance  
of the global barystatic sea level is large (63% and 81% for GRACE and SLB, respectively), meaning that, as expected, the  
North Atlantic resembles largely the global signal. Here, the trend accounts for about 60-80% of the total sea level trend,  
depending on the specific product used.

200 In the Mediterranean Sea, the interannual variability is the largest (more than 22 mm for all datasets) and does not follow the  
global signal (see the low percent explained variance in Table 3, especially for the interannual signal, no matter which dataset  
is considered). This suggests that the regional water cycle and sea level budget are disconnected to a large extent from the  
global one, and this is very likely due to the role of Gibraltar Strait (see e.g., Landerer and Volkov, 2013). Trends in the  
Mediterranean Sea are generally lower than in the other basins and explain about 45%, on average, of the total sea level trend.  
205 Remarkable peaks of the manometric sea level are visible in 2006, 2010, 2011, and 2018; for these events, GREP tends to  
underestimate the maxima compared to the other two datasets. All datasets indicate that the Mediterranean Sea manometric  
sea level has the largest average uncertainty.

### 3.2 Consistency between timeseries

The consistency between the three timeseries is investigated by decomposing the full signal in the interannual and subannual  
timeseries. The correlation matrix for the three temporal scales and the three basins is shown in Figure 2.

210 In the North Atlantic Ocean and in the Mediterranean Sea, the largest correlations are between SLB and GREP, all scales. The  
two datasets are not independent due to the use of altimetry and in-situ observations in both, so this result likely reflects their  
dependency. Correlations between GRACE and the other datasets are generally lower. At the interannual timescale, the  
correlation between GRACE and SLB is slightly larger (but the difference is not statistically significant) than that between  
GRACE and GREP, suggesting that for these regions SLB might capture the year-to-year variations better than the reanalyses.

215 At the subannual scale in the Mediterranean Sea, however, the consistency between GRACE and GREP is larger than that  
between GRACE and SLB (with a statistically significant difference), suggesting that the reanalyses capture the seasonal cycle  
better than SLB with respect to gravimetry data.

In the Arctic Ocean, a large consistency is found between GRACE and GREP; the correlations involving SLB are statistically  
significantly lower than the others, at all time scales (full, inter and subannual) at the 99% confidence level; this is also visible,  
220 in Figure 1, as fluctuations of the SLB timeseries not reproduced by the other two datasets. This suggests that in the Arctic  
Ocean, gravimetry and reanalyses are largely consistent. Investigating in detail the reason for such a result is beyond the scope  
of this paper; on the one hand, the meridional transports, sea-ice modeling, and atmospheric forcing, implicit in the reanalysis  
systems, are known to be able to shape the Arctic Ocean interannual variability realistically (see e.g. Mayer et al., 2016; 2019);  
on the other hand, altimetry and in-situ data are poorly sampled in the Arctic Ocean, making more challenging to apply the  
225 SLB approach therein.

### 3.3 Influence of climate indices on manometric sea level variations

Several climate indices are considered predictors for the manometric sea level in the three basins (Arctic Ocean, North Atlantic  
Ocean, and Mediterranean Sea). Their acronyms and meanings are listed in the caption of Figure 3. The detailed justification  
for inclusion in the analysis is provided by Pfeffer et al. (2022): through representing well-determined atmospheric circulation  
230 regimes, the indices synthesize the water cycle and the atmospheric forcing variability regimes, leading in turn to variations in  
the regional manometric sea level due to changes in oceanic divergence and freshwater forcing. For instance, the El Niño  
Southern Oscillation (ENSO) has a prominent role in modifying precipitation patterns, with obvious implications on the  
manometric sea level (e.g., Muis et al., 2018); changes in the North Atlantic Oscillation (NAO) modify atmospheric and

oceanic transports in North America and Europe, implying changes also in the Mediterranean Sea through modification to  
235 exchanges at Gibraltar and precipitation patterns (Landerer et al., 2013; Storto et al., 2019a). It is beyond the scope of this  
study to explain all possible modes of covariability, and the interested readers are referred to the specific literature for a broad  
overview (e.g., Andrew et al., 2006; Peralta-Ferriz et al., 2014; Merrifield et al., 2018; Volkov et al., 2019; Pfeffer et al., 2022).  
The North Atlantic manometric sea level is characterized by the largest impact of NPGO, consistently across all the datasets.  
While NPGO well explains variations in the eastern North Pacific Ocean (Di Lorenzo et al., 2008), its impact on the North  
240 Atlantic manometric sea level likely depends on the global barystatic signal and teleconnections (Iglesias et al., 2018). NPGO  
accounts for more than 25% of the North Atlantic manometric sea level variability, peaking at more than 40% for the SLB  
dataset. Significant impact in the North Atlantic manometric sea level is also given by variations described by the PDO, AMO,  
and IOD, although for the latter small consistency is found across the datasets.

In the Mediterranean Sea, the largest influence is provided by the Arctic Oscillation (AO), which explains more than 30% of  
245 the manometric sea level covariations for all datasets. AO is an expression of the North Atlantic variability, strictly linked to  
the NAO and closely linked to the North European wind circulation (e.g., Ambaum et al., 2001); while these are strictly  
connected, the regularization technique used here clearly indicates AO as a better predictor than NAO for the regional  
manometric sea level. Other influential climate modes of variability are linked to the North Pacific variability, namely the  
PDO and NPGO.

250 Finally, in the Arctic Ocean, the largest influence is found to be due to the Atlantic Multidecadal Oscillation (AMO), with  
values ranging from 25 to 35% depending on the dataset. AMO is known to modulate the sea-ice interannual variations and  
the Arctic amplification (Li et al., 2018; Fang et al., 2022), which are both important contributors to the sea level manometric  
fluctuations. IOD and NAO also significantly affect the Arctic manometric sea level, although the consensus between the  
datasets varies. The Arctic Oscillation is found influential when using the GRACE dataset consistently with previous studies  
255 (Peralta-Ferriz et al., 2014), although the other datasets show, in general, other preferences.

#### 4. Summary and Discussion

In this study, we have focused on the basin-averaged manometric sea level for a few regional basins (Arctic Ocean, North  
Atlantic Ocean, Mediterranean Sea) and from different datasets, to investigate the consistency, the emerging climate signals,  
the differences between the basin characteristics, and the link with the main large-scale modes of variability.

260 To the authors' knowledge, it is the first time that different datasets of manometric sea level from reanalyses, gravimetry, and  
altimetry minus in-situ data, are compared at the regional level to infer their strengths and weaknesses. The three basins (Arctic  
Ocean, North Atlantic Ocean, Mediterranean Sea) exhibit inherently different features, with the Mediterranean Sea showing,  
on average over the three products, the largest interannual variability, and the smallest trends; the Arctic Ocean shows large  
seasonal amplitude and trend, and the North Atlantic Ocean a pronounced seasonality and a quasi-linear trend, which is very  
265 well explained by the global barystatic signal. The three products are found in reasonable agreement, with all pairs significantly  
correlated at both inter- and subannual time scales. There are, however, non-negligible differences in the quantitative  
assessment; for instance, GRACE leads to a huge trend in the Arctic basin, peaking near the North Pole (not shown), which is  
not reproduced by either GREP or SLB and needs to be investigated in more detail; or a trend in the Mediterranean Sea smaller  
than the others.

270 In the Arctic Ocean, altimetry minus in-situ (SLB) is generally less in agreement with the other datasets based on correlation  
scores; this might be due to the poor altimetry and in-situ sampling, on which the SLB approach is based (see the PUM, Table  
1), which could be alleviated in reanalyses, to some extent, by the atmospheric forcing information and the meridional  
exchanges. In the Mediterranean Sea, subannual scale agreement is also the largest between GRACE and GREP with respect

275 to SLB, suggesting in turn that the Copernicus Marine Service global reanalyses can capture the manometric sea level variability in the studied regions.

Finally, a fingerprinting technique based on regularization in regression is used to quantify the influence of several large-scale climate modes of variability on the basin-averaged manometric sea level. In most cases, we found consistency in the results using the three different datasets. The analysis indicates the NPGO (North Pacific Gyre Oscillation), AO (Arctic Oscillation), and AMO (Atlantic Multidecadal Oscillation) to be the most influential modes for the North Atlantic Ocean, Mediterranean

280 Sea, and Arctic Ocean, respectively. This is the combined result of teleconnection patterns and cross-basin exchanges, as explained in detail in previous studies (Landerer and Volkov, 2013; Iglesias et al., 2018; Fang et al., 2022).

These results are intended to provide a summary of the manometric sea level variability within the three basins investigated here and to guide users in the choice of the specific product, depending on the region of interest. Further studies are needed to understand the different behavior of the datasets for certain aspects (e.g., the over-estimation of the Arctic Ocean manometric

285 sea level trend by GRACE, or its under-estimation in the Mediterranean Sea), namely whether this is due to some intrinsic limitations of the data processing, or the different processes implied by the measurement techniques.

#### *Data availability*

290 See Table 1 for accessing the data through the associated DOI.

#### *Author contribution*

AS designed the analysis and wrote most of the text; GC and AS performed the analysis; JP coordinated the processing of the manometric sea level data from GRACE, revised the manuscript, and provided many comments on the use of the observation-

295 based datasets and the fingerprinting technique; AB corrected in detail the Data and methods section; all authors contributed with data production and suggestions for improving the study.

1	GLOBAL_REANALYSIS_PHY_001_031 (GREP), numerical models	EU Copernicus Marine Service Product (2022a)	QUID (Quality Information Document): Desportes et al. (2022)  PUM (Product User Manual): Gounou et al. (2022)
2	Barystatic and manometric from satellite gravimetry (LEGOS - MAGELLIUM)	Aviso Odatis webpage, 2023: doi: <a href="https://doi.org/10.24400/527896/a01-2023.011">10.24400/527896/a01-2023.011</a>	PUM (Product User Manual): <a href="https://www.aviso.altimetry.fr/fileadmin/documents/data/products/indic/WAMBOR-DT-009-MAG_CopernicusMarine_ServiceEvolution_PUM_v2.0.pdf">https://www.aviso.altimetry.fr/fileadmin/documents/data/products/indic/WAMBOR-DT-009-MAG_CopernicusMarine_ServiceEvolution_PUM_v2.0.pdf</a>
3	Barystatic and manometric from sea level budget (LEGOS - MAGELLIUM)	Aviso Odatis webpage, 2023: <a href="https://doi.org/10.24400/527896/a01-2023.012">10.24400/527896/a01-2023.012</a>	PUM (Product User Manual): <a href="https://www.aviso.altimetry.fr/fileadmin/documents/data/products/indic/WAMBOR-DT-009-MAG_CopernicusMarine_ServiceEvolution_PUM_v2.0.pdf">https://www.aviso.altimetry.fr/fileadmin/documents/data/products/indic/WAMBOR-DT-009-MAG_CopernicusMarine_ServiceEvolution_PUM_v2.0.pdf</a>
4	SEALEVEL_GLO_PHY_L4_MY_008_047, L4 reprocessed altimetry observations	EU Copernicus Marine Service Product (2022b)	QUID (Quality Information Document): Pujol et al. (2023)  PUM (Product User Manual): Pujol (2022)

510 Table 1. Product Table

515

Region	Trend			Seasonal amplitude			Interannual variability			Average uncertainty		
	GREP	GRAC E	SLB	GREP	GRAC E	SLB	GREP	GRAC E	SLB	GREP	GRAC E	SLB
Arctic Ocean	2.45 +/- 0.45	6.19 +/- 0.87	0.97 +/- 0.46	33.5	12.3	33.3	18.1	26.7	21.8	0.17	0.48	0.06
North Atlantic Ocean	1.81 +/- 0.26	1.90 +/- 0.25	3.12 +/- 0.26	12.5	4.2	13.5	8.6	6.8	6.6	0.13	0.46	2.16
Mediterranean Sea	1.93 +/- 0.53	0.43 +/- 0.74	2.32 +/- 0.56	29.3	13.4	11.9	22.8	31.8	28.9	0.62	2.14	7.44

**Table 2.** Manometric sea level diagnostics for the three basins considered in this study, calculated from the three datasets GREP (ensemble mean), GRACE, and SLB. The trend is calculated as a linear fit, with uncertainty found through bootstrapping. Seasonal amplitude stems from fitting the detrended timeseries to a sinusoidal line, while interannual variability is the standard deviation of the timeseries without its trend and seasonal amplitude. Average uncertainty is calculated from the gridpoint values. For GREP, it is given by the ensemble standard deviation.

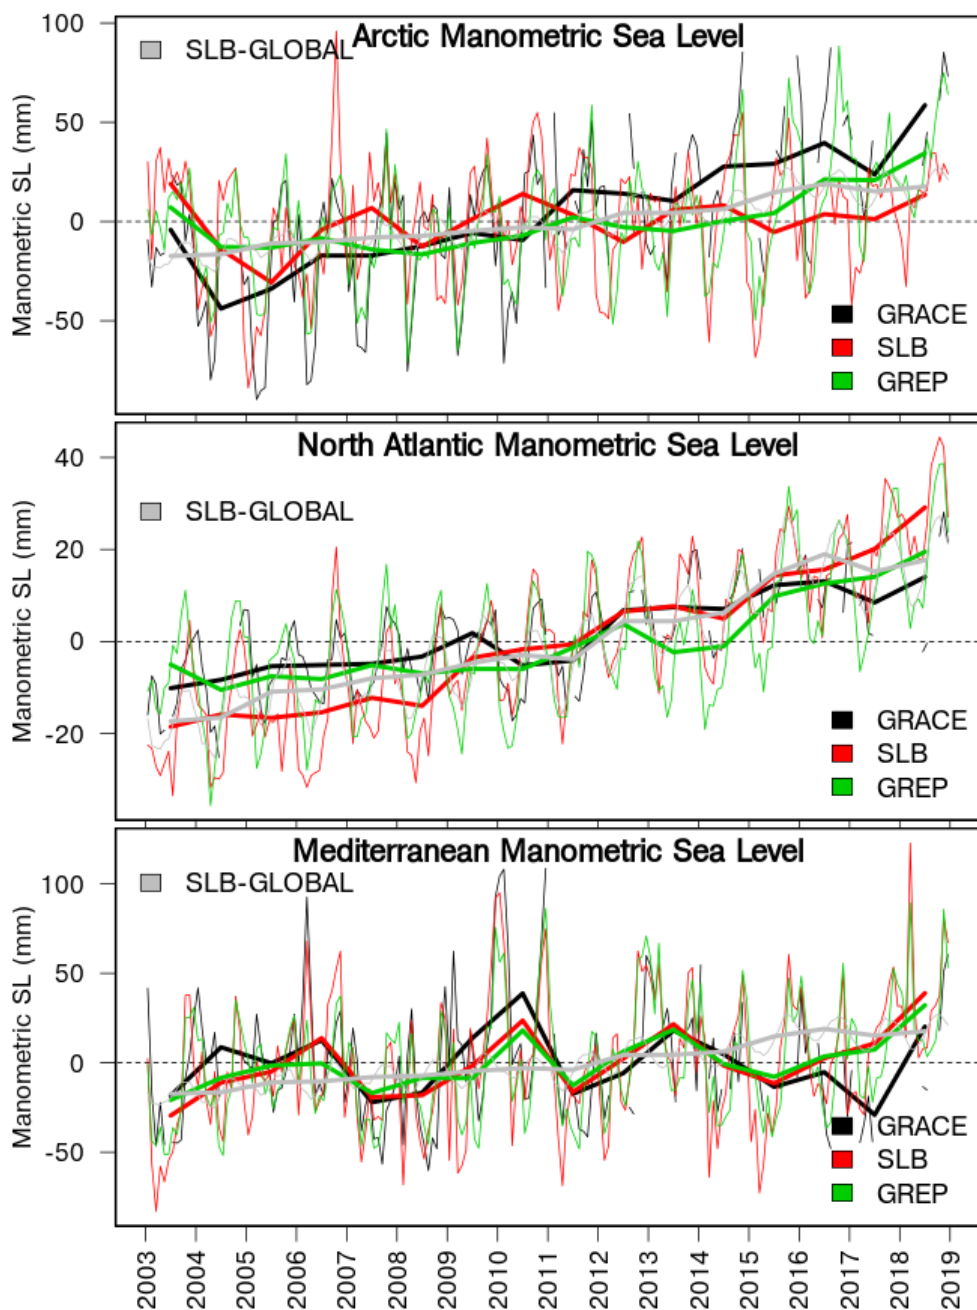

520

Region	Monthly timeseries		Interannual timescale		subannual timescale	
	GRACE	SLB	GRACE	SLB	GRACE	SLB
Arctic Ocean	61%	10%	45%	2%	91%	59%
North Atlantic Ocean	54%	83%	63%	81%	40%	90%
Mediterranean Sea	0%	18%	0%	10%	7%	59%

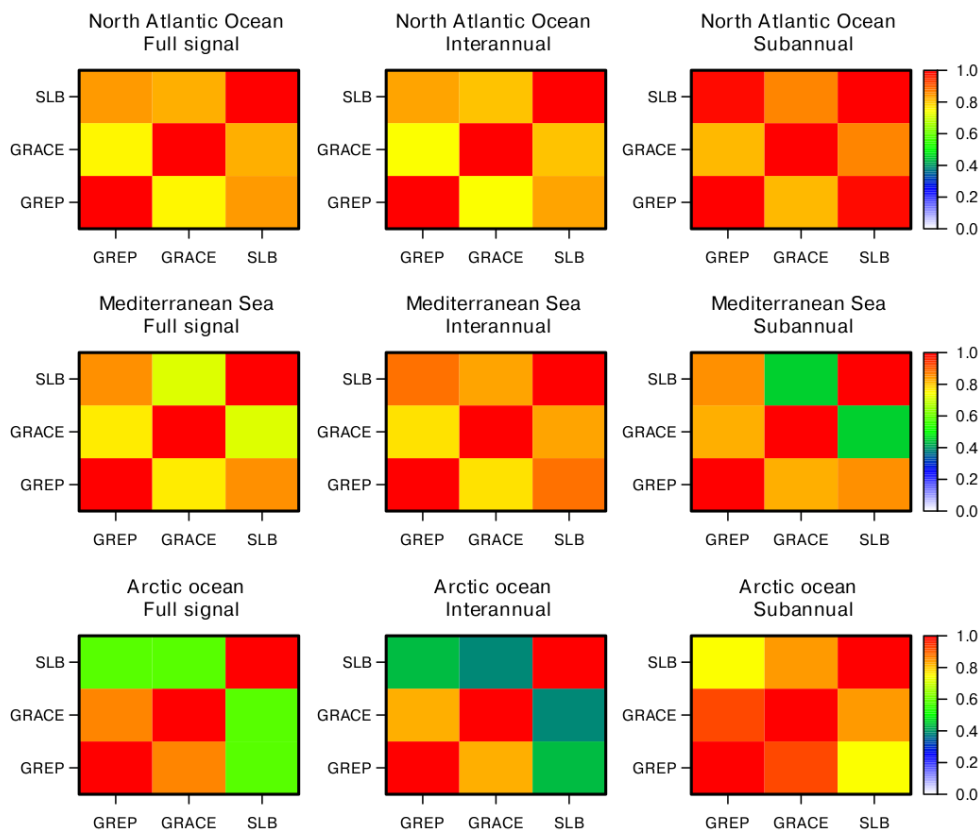

**Table 3.** Percent variance of the regional manometric sea level, explained by the global barystatic signal, namely the percent  $R^2$  coefficient for both the subannual and interannual signals. The global barystatic signal is shown in Figure 1 as gray lines.

525

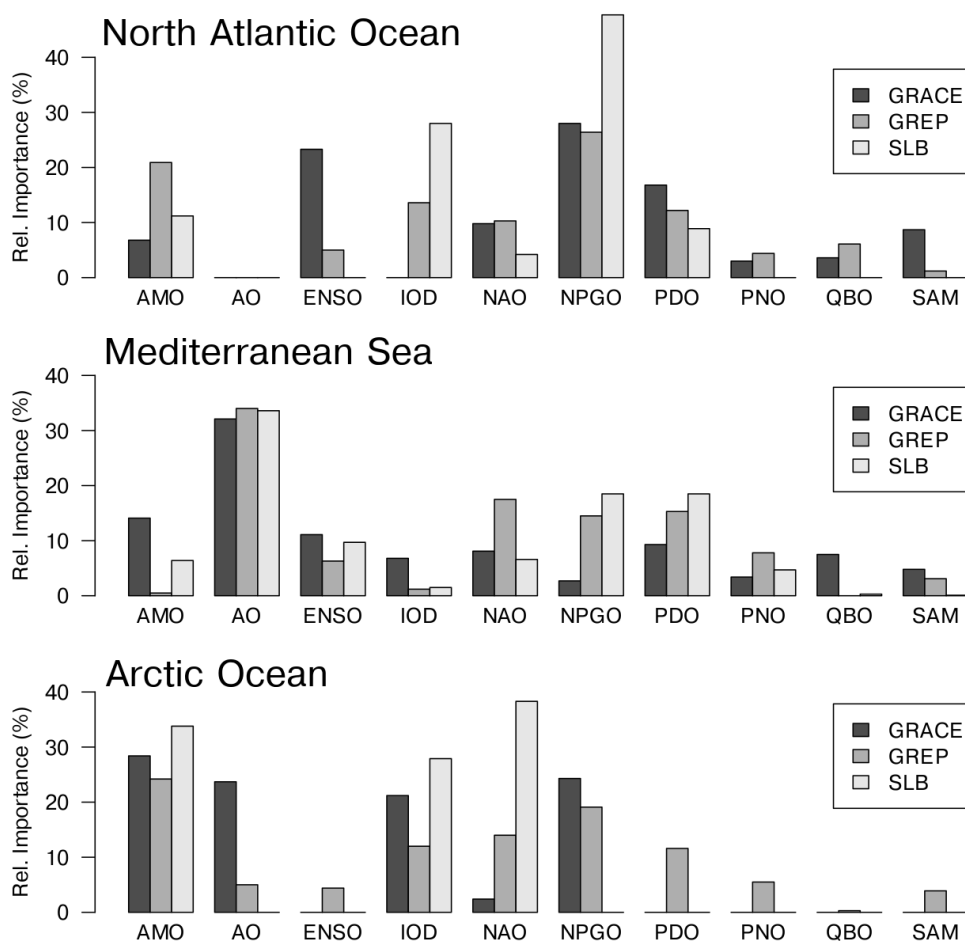

530 **Figure 1.** Manometric sea level timeseries for the Arctic, Mediterranean, and North Atlantic basins. Both monthly (thin lines) and yearly (thick lines) means are shown for GRACE, SLB, and GREP. The global barystatic sea level (SLB method) is also added in gray. The North Atlantic Ocean is defined from 0°N to 67°N, and the Arctic Ocean from 67°N in the Atlantic Ocean to the Bering Strait.

535 **Figure 2. Correlation matrix for the three datasets in the three ocean basins investigated in this study, for both the full, the interannual, and the subannual signal. All values of correlation are statistically significant, at the 99% confidence level.**

540

545 **Figure 3.** Relative importance (defined in the text in section 2.4) of the selected climate indices for the manometric sea level in the three basins investigated in this study, using the three datasets GRACE, GREP, and SLB. The climate indices acronyms are as follows: AMO: Atlantic Multidecadal Oscillation; AO: Arctic Oscillation; ENSO: multivariate El Niño Southern Oscillation; IOD: Indian Ocean Dipole; NAO: North Atlantic Oscillation; NPGO: North Pacific Gyre Oscillation; PDO: Pacific Decadal Oscillation; PNO: Pacific North American Oscillation; QBO: Quasi-Biennial Oscillation; SAM: Southern Annular Mode.
